

Mental Health and the Targeting of Social Assistance

Canishk Naik

[Latest version here](#)

ABSTRACT. People living with mental disorders are at a higher risk of needing income-support programs but face greater difficulty overcoming barriers to access. This paper investigates whether social assistance effectively reaches people with poor mental health. I measure mental health and social assistance take-up using Dutch administrative data and develop a theoretical framework to show how take-up responses can identify the marginal value of benefits (need) and the cost of barriers. These are key components for evaluating targeting effectiveness. I find that a policy increasing barriers disproportionately screens-out those with poor mental health, indicating a 65% higher cost of these barriers. Despite their higher cost, people with poor mental health have the same average take-up levels as those with good mental health, conditional on eligibility, which suggests greater need. To assess this, I show that individuals with poor mental health are more responsive to plausibly exogenous variation in benefits than those with good mental health, demonstrating that their need is twice as high. These estimates imply that people with poor mental health are inefficiently excluded from low-income welfare assistance by barriers. Consequently, reducing barriers to take-up would be twice as effective as increasing benefits.

I am incredibly thankful for all the advice and support given to me by my supervisors Nava Ashraf, Daniel Reck and Johannes Spinnewijn. This project also benefited greatly from insightful discussions with Sonia Bhalotra, Jonneke Bolhaar, Katie Brown, Gharad Bryan, Francesco Caselli, Gaby Deschamps, Matthias Doepke, Jack Fisher, Nilmini Herath, Amen Jalal, Xavier Jaravel, Camille Landais, Gabriel Leite Mariante, Kristóf Madarász, Joana Naritomi, Will Parker, Michelle Rao, Patrick Schneider, Kate Smith, Caterina Soto Vieira, Krishna Srinivasan, Neil Thakral, Timo Verlaat, Heike Vethaak, Jenny Wang, Sarah Winton, Alwyn Young, Alice Zulkairnan and seminar participants at the CPB, IFS, IIPF and LSE. I gratefully acknowledge financial support from STICERD (Grant #108968) and from the Economic and Social Research Council DTP (Grant #ES/P000622/1).

1. INTRODUCTION

Poor mental health is an urgent societal issue. Almost 1 billion people live with a mental disorder (WHO, 2022). In 2010, the economic cost of mental illness due to lost productivity and bad health was estimated to be \$2.5 trillion, and is expected to more than double by 2030 (Bloom et al., 2012). Symptoms of mental disorders include worthlessness, confused thinking, withdrawal from support networks, fear, fatigue, guilt and, in the extreme case, suicidality (APA, 2013). Additionally, people with poor mental health face up to three times the risk of poverty (Ridley et al., 2020). Therefore, people struggling with mental disorders are especially vulnerable.

Modern welfare states are rooted in the principle that society should protect its most vulnerable members. Ensuring that safety net programs effectively reach those in need is essential to upholding the social contract. However, administrative and psychological costs often make it difficult to access social support, which leads to widespread non-take-up (Ko and Moffitt, 2024). In theory, application barriers could help filter out people with lower need (Nichols and Zeckhauser, 1982), but in practice people suffering from mental illness find it more challenging to overcome take-up barriers than those with good mental health (Bell et al., 2022).

This paper investigates whether social assistance effectively reaches people with poor mental health. A key concern is that the very source of vulnerability is also what makes it difficult to overcome barriers to help. Nevertheless, the inefficiency arising from the exclusion of individuals with mental disorders from assistance has remained undocumented.

Mental disorders pose important theoretical and empirical challenges in determining effective targeting. I focus on low-income welfare benefits in this study. Theoretically, eligibility for these programs is determined by people having few resources. The goal of barriers is then to target for *general* unobservable need. Poor mental health affects *cost* of barriers as well as, in principle, *need* for support. The challenge is that both need and cost affect take-up, however separating need from cost is essential for assessing effectiveness. This is because barriers target well if the more needy can afford the cost and the less needy cannot. This theoretical challenge applies to the wide range of social programs

where eligibility does not directly depend on mental health but the eligible population contains many people with mental disorders.¹ Empirically, measuring mental health at scale is challenging with survey data (due to small samples and under-reporting because of stigma (Bharadwaj et al., 2017)) but also with administrative data (extreme outcomes are unlikely and people with poor mental health often do not use care (Cronin et al., 2024)).

I address these challenges in three steps. First, I develop a theoretical framework to disentangle need for benefits from the cost of overcoming barriers using take-up responses to changes in benefits and barriers. Second, I empirically estimate take-up levels and responses of low-income benefits, heterogeneously by mental health, using Dutch administrative data. The data contain rich information on mental health from administrative sources and a large ($N \approx 400k$) linked survey, as well as on social assistance eligibility and take-up. Finally, I combine theory and empirics to calculate how need and cost vary with mental health and evaluate welfare effects of the targeting of social assistance.

The key theoretical finding of this paper is that combining differences in average take-up levels across groups with take-up responses to changes in benefits and barriers is sufficient to evaluate the marginal value of benefits (need) and the cost of barriers. To show this, I develop a theoretical framework allowing for heterogeneity in both need and cost.² There are three components to identification. (i) Differences in average take-up levels reflect how *average* value net of cost compares across the population. (ii) If an individual responds more to a change in barriers, either they have higher cost (sensitivity to barriers) or they were at the margin of taking-up versus not (i.e. average value net of cost closer to 0. This can be isolated by difference in take-up levels). (iii) Similarly, large responses to changes in benefits reflect either high need (high *marginal* value) or average value net of cost ≈ 0 , but the latter can be separated-out using difference in take-up levels.

Identifying how the need for benefits and the cost of overcoming barriers depend on mental health is crucial for policy-making. The former is the social welfare gain from

¹The exception is disability insurance. Here, Godard et al. (2022); Haller and Staubli (2024) emphasize that the key policy challenge with mental disorders is that they are hard for case-workers to observe.

²In the framework, need and cost can vary across people with the same income. Thus, need cannot be controlled for by holding income constant, creating a new identification challenge relative to past work on targeting (Finkelstein and Notowidigdo, 2019; Raffkin et al., 2023).

transferring €1 from someone with good mental health to someone with poor mental health. The latter reflects the welfare costs that overcoming barriers imposes on individuals. Therefore, these key primitives characterise the benefits and costs of targeting social assistance using barriers. For example, need, cost and take-up responses to benefits and barriers are sufficient to calculate the welfare effects of a budget-neutral increase in barriers, where the money saved due to lower take-up is used to finance an increase in benefit level.³

Empirically, I study social assistance take-up and mental health using administrative data for the population of the Netherlands (17 million people). I examine the flagship Dutch social assistance program, the *algemene bijstand*,⁴ a cash transfer designed for people who don't have enough money to subsist. I combine detailed information on socioeconomic demographics for the years 2011 - 2020 to construct an accurate measure of eligibility with low measurement-error.⁵ Furthermore, the data contain rich mental health information, coming from three classes of outcomes: care usage, extreme outcomes and subjective mental health from a large survey which is linked to the administrative data.⁶ I combine these outcomes to reliably proxy for mental health status: this is not possible with survey or admin data alone (Kolstad et al., 2024).

Three key findings arise from my empirical analysis. The first is descriptive. I find that people with poor mental health are substantially more likely to be eligible for social assistance than those with good mental health, however, conditional on eligibility, they take-up at the same rate. I find that one quarter of people eligible for social assistance have been diagnosed with a mental disorder, more than double the rate for the general

³This is an example of a policy experiment which captures the essence of how effective it is to use barriers to target (Zeckhauser, 2021; Ko and Moffitt, 2024).

⁴Literal translation: general assistance. Information about the benefit can be found on the Dutch Government website. I will refer to this program as social assistance (SA). Social assistance is more prevalent than unemployment or disability benefits, with around 400,000 recipients every year. Eligibility is primarily determined by income being below 100% of the full-time net minimum monthly wage for couples (70% for singles).

⁵Accurately calculating eligibility is a key challenge facing the take-up literature (Ko and Moffitt, 2024). I find that the probability of a Type-II error is small: the estimated $\mathbb{P}[SA | \text{Ineligible}] = 1\%$.

⁶The outcomes are: care usage (mental healthcare spending, dispensations of psychotropic drugs), extreme outcomes (hospitalisations for a mental health condition, deaths by suicide) and subjective mental health from a large survey (psychological distress, loneliness and perceived control over own life).

population. However, the average take-up levels (60%) do not meaningfully differ by mental health status conditional on eligibility, income and other covariates.

Second, increases in barriers to accessing social assistance disproportionately screen out people with poor mental health. I estimate the effect of the Participation Act ([Ministerie van SZW, 2015](#)) on the take-up of social assistance, a policy which increased access barriers by intensifying the obligations that recipients have to satisfy and increasing incentives for municipalities to restrict inflow ([SCP, 2019](#)). The act increased the compliance costs from obligations and the psychological costs from unpleasant interactions with the municipality ([Ministerie van SZW, 2022](#)). Using a difference-in-differences design, I show that the policy reduces receipt of social assistance by people with poor mental health relative to good. These results are driven exclusively by deterrence of inflow, which decreases by 10% vs baseline inflow for good mental health.

Third, people with poor mental health respond twice as much to a change in benefits than those with good mental health. Social assistance in the Netherlands tops-up income to an eligibility threshold, which implies a kinked benefits-schedule as a function of income (100% marginal tax rate below the threshold, 0% above). I exploit this kinked schedule using a regression kink design to identify the effect of benefit level on take-up, heterogeneously by mental health. I estimate elasticities of social assistance receipt with respect to benefits of 0.76 and 0.29 for poor and good mental health, respectively.

Combining theory and empirical estimates yields the final key finding of the paper: people with poor mental health need benefits twice as much as those with good mental health, conditional on income, but also have a 65% higher cost of overcoming barriers. These primitives suggest that governments have an incentive to redistribute money to people with poor mental health, but that barriers are not an efficient way to do so. I estimate the marginal value of public funds ([Hendren and Sprung-Keyser, 2020](#)), capturing the direct effect of the policy divided by government cost, of a reduction in barriers as 1.88 and of an increase in benefits as 0.82. This implies reducing barriers is an effective use of government funds, $2.1 \times$ more so than increasing benefits.

Contribution to the Literature: This paper contributes to the public economics literature on the targeting of government programs. [Nichols and Zeckhauser \(1982\)](#) argue that

ordeals, or costly barriers to take-up, can screen for need if the correlation between need and these costs is weakly negative. Some empirical studies support this, showing barriers effectively target aid ([Alatas et al., 2016](#); [Giannella et al., 2023](#); [Wu and Meyer, 2023](#)). Indeed, [Rafkin et al. \(2023\)](#) find that self-targeting is valuable from a social welfare perspective. However, targeting through ordeals can be undermined by take-up frictions among the needy ([Deshpande and Li, 2019](#); [Finkelstein and Notowidigdo, 2019](#); [Homonoff and Somerville, 2021](#)) or adverse selection ([Shepard and Wagner, 2022](#)). Generally in this literature, need is seen as arising from low-income.

I take a new approach and focus specifically on mental health. To my knowledge, this is the first paper to assess the welfare consequences of excluding those with poor mental health from assistance. Although the behavioural public policy literature has examined the descriptive relationship between mental health and the take-up of social programs ([Arulsamy and Delaney, 2022](#); [Bell et al., 2022](#); [Martin et al., 2023a,b](#)), welfare effects require an assessment of need. I show that people suffering from mental disorders need benefits more than those with good mental health, even conditional on having the same income. This highlights that vulnerability is often multi-dimensional and goes beyond poverty. My results show that despite their higher need, people with poor mental health are disproportionately screened-out by barriers, implying inefficient targeting.

The idea that mental disorders both increase need and make it harder to navigate barriers to assistance mirrors the dual effects highlighted in the scarcity literature ([Mullainathan et al., 2012](#)). Financial strain can impair cognition ([Mani et al., 2013](#); [Kaur et al., 2021](#)), yet it can also sharpen focus and lead to better decisions ([Shah et al., 2012](#); [Fehr et al., 2022](#)). This paper develops a theoretical framework showing how to discipline these opposing forces and implements the identification empirically using rich administrative data and policy variation in benefits and barriers.

Lastly, there is a growing literature in psychology and economics studying mental disorders. Poor mental health not only imposes cognitive burden ([Bierman et al., 2008](#); [Hammar and Årdal, 2009](#)) but also impairs emotion regulation ([Gross and Muñoz, 1995](#)), both of which hinder everyday functioning ([Kessler et al., 2003](#); [Evans et al., 2014](#)). In economics, studies demonstrate that mental healthcare interventions, such as psychotherapy and

mindfulness, improve self-confidence, patience, risk-tolerance and reduce decision costs (Bhat et al., 2022; Shreekumar and Vautrey, 2021; Angelucci and Bennett, 2024a,b). The literature also explores how mental healthcare affects economic outcomes (Barker et al., 2021; Baranov et al., 2020; Serena, 2024) and how income impacts mental health (Christian et al., 2019; Miller et al., 2024; Schmidt et al., 2021; Silver and Zhang, 2022).

I quantify the policy relevance of the cognitive and emotional burdens that mental disorders impose on individuals by empirically estimating the welfare costs of ordeals for these people. Moreover, I use a revealed-preference approach as in Deshpande and Lockwood (2022); Haller and Staubli (2024) to show that people with poor mental health have a higher *perceived* need for welfare benefits than those without mental disorders. This new finding shows that non-take-up of assistance among people with poor mental health does not stem from under-valuation, but rather the challenges of accessing benefits.

These results support Sen’s “capabilities approach” (Sen, 1999, 2008); those facing greater daily challenges, such as disabilities, require more resources to satisfy basic needs. My analysis indicates that the same cognitive bandwidth and emotion regulation constraints that heighten the costs of overcoming barriers also appear to exacerbate everyday stressors enough to significantly raise the marginal value of additional income.

Outline: Section 2 sets out my theoretical framework to characterize the social welfare consequences of targeting. In Section 3, I describe the context and data. I quantify social assistance take-up levels by mental health status in Section 4. I estimate take-up responses to changes in barriers in Section 5 and benefits in Section 6. Section 7 combines the theory and empirical estimates to calculate welfare effects. Section 8 concludes.

2. THEORETICAL FRAMEWORK

I adapt the model from Finkelstein and Notowidigdo (2019). I allow for heterogeneous marginal value of €1 (need), even across individuals with the same income or consumption. This generalisation is motivated by the vulnerability of people with poor mental health going beyond their risk of poverty. I propose a method for separately isolating need from the cost of overcoming barriers using take-up responses to changes in benefits

and barriers.⁷ The framework yields empirically-implementable formulas for the welfare effects of targeting. Proofs and extensions are in [Appendix A](#).

2.1. Model of Social Assistance Take-up.

2.1.1. *Setup*. Individuals are indexed by θ .⁸ Social assistance is defined by two policy parameters. B is the (monetary) benefit, Λ is the barrier that individuals have to overcome to receive B . Each θ makes one key choice: whether to receive social assistance:

$$SA = \mathbb{1}\{\text{overcome barrier } \Lambda \text{ to receive benefit } B\} \quad (2.1)$$

Preferences are defined as follows. Individuals derive value $v_\theta(B)$ from benefits B . There is an take-up cost $\kappa_\theta(\Lambda)$, which represents the individual-specific dis-utility from overcoming barrier Λ . I also model take-up to depend on an independent additive choice-shock $\varepsilon \sim F$ which can be thought of as decision-relevant unobservables which are unaffected by policy. Therefore, the take-up equation for each θ is:

$$SA = 1 \iff v_\theta(B) > \kappa_\theta(\Lambda) + \varepsilon \quad (2.2)$$

This means that behaviour follows a threshold-rule: if $\varepsilon \leq \varepsilon_\theta^* = v_\theta(B) - \kappa_\theta(\Lambda)$, $SA = 1$ and if $\varepsilon > \varepsilon_\theta^*$, $SA = 0$. Therefore, rate of receipt is given by:

$$\mathbb{P}[SA]_\theta = F(v_\theta(B) - \kappa_\theta(\Lambda)) \quad (2.3)$$

This model takes a stylised reduced-form revealed-preference approach, where individual values and costs are modelled as catch-all quantities that could arise from various psychological factors and are reflected by behaviour. Given the limited evidence on welfare effects for individuals with poor mental health, simplicity is crucial. As such, I minimise structural assumptions and focus on identifying the key statistics that are sufficient for policymakers to assess targeting effectiveness.

⁷This distinction relates to [Shepard and Wagner \(2022\)](#), who show that adverse-selection can undermine ordeal-mechanisms due to the correlation between value and cost. Importantly - in their setting cost refers to cost of insurance (borne by the government), whereas I focus on the cost of ordeals (borne by the individual).

⁸In my empirical setting, θ will represent mental health status, but the following model applies to any other dimension of heterogeneity which could influence the marginal value of €1 as well as the take-up cost.

Nevertheless, [Appendix A](#) presents a micro-foundation of $v_\theta(B)$ for completeness. Value arises from extra consumption and recovered costs of work. Income depends on take-up but is fixed otherwise: $y_\theta^{SA=1}$ refers earned-income while receiving social assistance and $y_\theta^{SA=0}$ represents earned-income when not. All income (including benefits) is taxed at marginal tax rate τ .

2.2. Welfare.

2.2.1. *Individual Welfare.* Denote U_θ as θ 's utility (which depends on take-up), and \mathcal{U}_θ expected utility. Following the setup in [Section 2.1.1](#), I normalise utility to 0 if $SA = 0$.

$$\begin{aligned}\mathcal{U}_\theta &= \mathbb{E}[U_\theta] = \mathbb{P}[SA]_\theta \cdot \mathbb{E}[\text{Utility} | SA = 1] + (1 - \mathbb{P}[SA]) \cdot \underbrace{\mathbb{E}[\text{Utility} | SA = 0]}_{\text{Normalised to 0}} \\ &= \int_{-\infty}^{\varepsilon_\theta^*} [v_\theta(B) - \kappa_\theta(\Lambda) - \varepsilon] dF(\varepsilon)\end{aligned}$$

where $\varepsilon_\theta^* = v_\theta(B) - \kappa_\theta(\Lambda)$. Importantly, this formulation assumes rationality.⁹

2.2.2. *Social Welfare.* Let $\mu(\theta)$ be the distribution of types, and λ_θ social welfare weights. The government's problem is given by:

$$\begin{aligned}W &= \max_{\Lambda, B} \int \lambda_\theta \mathcal{U}_\theta d\mu(\theta) \\ \text{s.t. } \underbrace{\int \tau y_\theta^{SA=0} \cdot (1 - \mathbb{P}[SA]_\theta) + \tau(y^{SA=1} + B) \cdot \mathbb{P}[SA]_\theta d\mu(\theta)}_{\text{Tax Revenue}} &= \underbrace{\int B \cdot \mathbb{P}[SA]_\theta d\mu(\theta)}_{\text{Program Costs}}\end{aligned}\quad (2.4)$$

In this framework, I assume eligibility criteria for benefits are fixed (though not explicitly modelled).¹⁰ τ is also fixed. The government does not observe individuals' private types (θ, ε) , making targeted policy design challenging. Instead, it must rely on blunt instruments—benefit levels (B) and barriers to access (Λ)—which do not vary by θ to indirectly target those most in need. The policy-maker's goal is to allocate benefits to

⁹See [Section 2.3.2](#) for a discussion of all key assumptions.

¹⁰I discuss how to explicitly model eligibility in detail in [Appendix A](#).

individuals with a high, unobservable marginal value of benefits ($v'_\theta(B)$, i.e., need). Barriers (Λ) effectively target when neediest receive assistance, while those with lower need do not. [Section 2.2.3](#) derives formulas for the welfare effect of an example policy experiment capturing this mechanism.¹¹ This is one way of characterising the effectiveness of targeting using barriers.

2.2.3. Welfare Effects of a Budget-Neutral Increase in Barriers. I consider a policy experiment capturing the essence of using barriers to target social assistance: increase barriers, saving government funds due to lower take-up, in order to finance an increase in benefit level. This is a budget neutral increase in Λ (B adjusts).

Proposition 2.1. *The marginal welfare effect of a budget-neutral increase in ordeals financing an increase in benefits is given by:*

$$\frac{dW}{d\Lambda} = \int \lambda_\theta \mathbb{P}[SA]_\theta \left[\underbrace{v'_\theta(B)}_{\text{Need}} \cdot \frac{dB}{d\Lambda} - \underbrace{\kappa'_\theta(\Lambda)}_{\text{Cost}} \right] d\mu \quad (2.5)$$

Budget Neutrality implies:

$$\frac{dB}{d\Lambda} = \frac{- \int FE_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda} d\mu}{(1 - \tau) \cdot \int \mathbb{P}[SA]_\theta d\mu + \int FE_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial B} d\mu} \quad (2.6)$$

where:

$$FE_\theta = \tau \cdot (y_\theta^{SA=0} - y_\theta^{SA=1}) + (1 - \tau) \cdot B \quad (2.7)$$

[Equation \(2.5\)](#) follows from an application of the Envelope Theorem. The expression shows that the overall welfare effect is large whenever take-up is high ($\mathbb{P}[SA]_\theta$ large) among the θ 's with the highest need (v'_θ large) and *lowest* ordeal-costs (κ'_θ small). Analogously, $\frac{dW}{d\Lambda}$ will be negative when need and cost are strongly positively correlated.

The intuition behind [Equation \(2.6\)](#) is as follows. Budget-neutral policy changes depend on aggregate responses only. The government can increase B more if *more* people are screened out by ordeals, if people take-up *less* in response to changes in benefit level and if there are *fewer* beneficiaries at baseline. FE_θ is the fiscal externality of θ applying:

¹¹See, e.g. [Ko and Moffitt \(2024\)](#) who say that the “presence of costs induces the less needy to not apply, which saves government funds that can then be used to pay higher benefits to those in greater need, who have a higher probability of ending up as recipients.”

there is a moral hazard fiscal externality due to labour supply response $y^{SA=0} \rightarrow y^{SA=1}$ which costs the government $\tau(y^{SA=0} - y^{SA=1})$, and a direct cost $(1 - \tau)B$ paid out to θ .

The welfare effects depend on four key sufficient statistics. Increasing barriers imposes a direct cost on infra-marginal individuals: $\kappa'_\theta(\Lambda)$. However, the government saves money due to lower take-up. This depends on the strength of *barrier screening effects*, $\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}$. Increasing benefits has redistributive value for infra-marginal individuals: $v'_\theta(B)$. However, it costs the government money. This depends on the strength of *benefit take-up effects*, $\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}$.¹²

$\frac{dW}{d\Lambda}$ is my overall metric for the social welfare consequences of targeting using ordeal mechanisms. However, the units are hard to interpret. I use the framework of [Hendren and Sprung-Keyser \(2020\)](#) to aid intuition by also deriving the marginal value of public funds (MVPF) of a decrease in barriers vs an increase in benefit level. The MVPF is defined as willingness-to-pay divided by government cost (both money-metric). The formulae for the MVPF of dB and $d\Lambda$ are derived in [Appendix A.1](#). While MVPFs have interpretable units, they do not capture θ 's having different marginal values of income unless social welfare weights are included. This is why I derive both formulations.

2.3. Identification. How should we empirically characterise the welfare consequences of targeting using barriers? [Proposition 2.1](#) is an example showing that in order to know whether barriers target effectively, we must estimate four key “sufficient statistics”: need (v'_θ), cost (κ'_θ), benefit take-up effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}\right)$ and barrier screening effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}\right)$.¹³

My goal is to quantify these statistics empirically. Therefore, it is helpful if there are as few as possible. First, I use theory to reduce the number of sufficient-statistics from 4 to 3. The key idea is that benefit take-up effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}\right)$ depend on the marginal value of benefits, i.e. need (v'_θ). Similarly, barrier screening effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}\right)$ depend on the cost of barriers (κ'_θ).

¹²The policy experiment differs from [Rafkin et al. \(2023\)](#) in what we compare ordeal-costs $\kappa_\theta(\Lambda)$ to. They consider moving to automatic enrolment (comparing $\kappa_\theta(\Lambda)$ to 0) whereas I consider reducing barriers (comparing $\kappa_\theta(\Lambda)$ to $\kappa_\theta(\Lambda - \delta\Lambda)$). Hence, I require variation in barriers as well as benefits.

¹³Therefore, my model aligns with the sufficient-statistics approach to public economics ([Einav and Finkelstein, 2011](#); [Baily, 1978](#); [Chetty, 2008](#)).

Remark 2.1. Barrier screening effects are characterised by Equation (2.8), and benefit take-up effects by Equation (2.9).

$$\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda} = -\kappa'_\theta \cdot f_\varepsilon(v_\theta - \kappa_\theta) \quad (2.8)$$

$$\frac{\partial \mathbb{P}[SA]_\theta}{\partial B} = v'_\theta \cdot f_\varepsilon(v_\theta - \kappa_\theta) \quad (2.9)$$

Intuitively, Λ is a price of taking up. Therefore, responsiveness to take-up is large when consumers are price-responsive (κ' large) or just at the margin of take-up ($f_\varepsilon(\cdot)$ large). Similarly, responsiveness to a change in benefit level is governed by need (v') and the probability of being marginal. This means that there are only three key primitives which determine welfare effects: need, cost and $f_\varepsilon(v_\theta - \kappa_\theta)$, the likelihood of being on the margin of take-up. The latter is an extrapolation term allowing for the inference of infra-marginal costs/benefits through marginal take-up responses.

2.3.1. Three-step Identification. In this section, I present a three-step method to identify the three key statistics sufficient for evaluating welfare effects. The method takes as inputs: take-up levels $\mathbb{P}[SA]_\theta$, barrier screening effects $\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}$ and benefit take-up effects $\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}$ and uses these to identify need (v'_θ), cost (κ'_θ) and the likelihood of being marginal ($f_\varepsilon(v_\theta - \kappa_\theta)$). The intuition is as follows:

Difference in take-up levels $\mathbb{P}[SA]_\theta$ across types cannot distinguish between average value (v_θ) and cost. However, they reflect how average value *net* of cost compares across types. This, in turn, influences how $f_\varepsilon(v_\theta - \kappa_\theta)$ compares across types. Using this information, cost can be inferred from barrier screening effects $\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}$. The idea is that $\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}$ being large reflects either large κ' or average value net of cost being close to zero. The latter can be isolated using difference in take-up levels. Similarly, the contribution of $f_\varepsilon(v_\theta - \kappa_\theta)$ to benefit take-up effects $\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}$ can be isolated from need.

Step 1 (Average take-up levels): To aid intuition, suppose that we are in a special case of equalised take-up levels: $\mathbb{P}[SA]_\theta = \mathbb{P}[SA]_{\tilde{\theta}}$.¹⁴ I.e. $F(v_\theta - \kappa_\theta) = F(v_{\tilde{\theta}} - \kappa_{\tilde{\theta}})$. Then, $f(v_\theta - \kappa_\theta) = f(v_{\tilde{\theta}} - \kappa_{\tilde{\theta}})$ because the cdf F is monotonic. More generally if $\mathbb{P}[SA]_\theta \neq \mathbb{P}[SA]_{\tilde{\theta}}$, $f(v_\theta - \kappa_\theta)$

¹⁴This is motivated by the empirical application, where I find no meaningful difference in average take-up levels by mental health.

is identified in terms of $f(v_{\tilde{\theta}} - \kappa_{\tilde{\theta}})$ using a first-order Taylor expansion of difference in average take-up levels $\mathbb{P}[SA]_{\theta} - \mathbb{P}[SA]_{\tilde{\theta}}$. This requires additional structure, and is set out in [Appendix A.2](#). At the end of **Step 1**, we know how $f(v_{\theta} - \kappa_{\theta})$ compares across types.

Step 2 (Benefit take-up effects): If we know how $f(v_{\theta} - \kappa_{\theta})$ compares across types, and estimate benefit take-up effects for each type - then we can quantify how need varies across types. This done by dividing [Equation \(2.9\)](#) across types to give:

$$\frac{\frac{\partial \mathbb{P}[SA]_{\theta}}{\partial B}}{\frac{\partial \mathbb{P}[SA]_{\tilde{\theta}}}{\partial B}} = \frac{v'_{\theta}}{v'_{\tilde{\theta}}} \cdot \underbrace{\frac{f_{\varepsilon}(v_{\theta} - \kappa_{\theta})}{f_{\varepsilon}(v_{\tilde{\theta}} - \kappa_{\tilde{\theta}})}}_{\text{Estimated in Step 1}} \quad (2.10)$$

Then, if we normalise $v'_{\theta_0} = 1$ for some θ_0 we calculate v'_{θ} for all other θ using [Equation \(2.10\)](#). This normalization is without loss, and effectively scales all welfare effects in terms of θ_0 's WTP for €1.¹⁵

Step 3 (Barrier screening effects): Finally, divide barrier screening effects from [Equation \(2.8\)](#) by benefit take-up effects from [Equation \(2.9\)](#) within type to identify κ'_{θ} for all θ as follows:¹⁶

$$\frac{\frac{\partial \mathbb{P}[SA]_{\theta}}{\partial \Lambda}}{\frac{\partial \mathbb{P}[SA]_{\theta}}{\partial B}} = \kappa'_{\theta} \cdot \underbrace{\frac{1}{v'_{\theta}}}_{\text{Estimated in Step 2}} \quad (2.11)$$

2.3.2. Discussion of Key Assumptions. Before presenting the empirical analysis, it is important to discuss the key assumptions underlying the identification of need and cost. In [Section 7](#), I return to these assumptions and characterise how relaxing them impacts welfare effects.

I assume that ε is an additive independent shock to the take-up equation: $SA = 1 \iff v_{\theta} > \kappa_{\theta} + \varepsilon$. Independence, as assumed in random utility models ([McFadden, 1981](#); [Woodford, 2020](#)), enables **Step 1** in the identification. The assumption can be probed by examining how including additional covariates changes the three-step identification.¹⁷ Without

¹⁵ v'_{θ} is then understood as θ 's need relative to θ_0 .

¹⁶This within-type identification method is as in [Haller and Staubli \(2024\)](#), but the across-type identification is new. Here, the key novelty is that I can estimate take-up levels with information on eligibility and use these to inform differences in likelihood of being on the margin of take-up across types.

¹⁷Throughout my empirical analysis, including additional covariates does not meaningfully change the comparison between good and poor mental health, providing support for $\varepsilon \perp \theta$.

independence, the model is not identified and either v_θ constant across θ or κ_θ constant across θ must be assumed. Seeing as the purpose of the framework was to separate need and cost when both could depend on mental health, neither of these cases is useful.¹⁸ Additivity allows me to separate need/cost from the extrapolation term $f_\varepsilon(v_\theta - \kappa_\theta)$ in Equations (2.8) and (2.9).

The framework assumes that the likelihood of being on the margin of take-up, $f(v_\theta - \kappa_\theta)$, is the same for benefit and barrier instruments. This comes from θ and ε being one-dimensional. The assumption is called into question by recent work arguing that the compliers to an instrument depend on the instrument itself (Kline and Walters, 2019; Mogstad et al., 2024). This assumption allows for minimal structure on the take-up equation. Relaxing $f(v_\theta - \kappa_\theta)$ to depend on the instrument is possible under additional parametric assumptions as long as $f(v_\theta - \kappa_\theta) = f(v_{\tilde{\theta}} - \kappa_{\tilde{\theta}})$ for all $\theta, \tilde{\theta}$, i.e. as long as the difference in complier characteristics across instruments is orthogonal to mental health. Appendix E shows welfare effects in this case.

In the theory, θ is treated as an immutable type, but in practice mental health evolves over time and in response to stimuli. This assumption is made in order to set out a tractable static framework. In Section 6, I show that social assistance does not appear to have a strong dynamic positive effect on mental health. However, ordeals likely worsen mental health, a dynamic I cannot quantify in this paper. This effect would imply that the welfare costs of increasing ordeals are a lower-bound.

Finally, I use a revealed-preference framework. Assuming rationality allows me to reveal need and cost from take-up responses, and to use the Envelope Theorem when deriving welfare effects. In Section 7, I follow the framework developed by Naik and Reck (2024) to characterise how confident the government needs to be about bias to reverse the estimated sign of the welfare effects.

The rest of the paper is devoted to evaluating the key sufficient statistics and discussing implications for welfare. In Section 4, I estimate average take-up levels and show that they do not meaningfully differ by mental health. I estimate barrier screening effects in Section 5 and benefit take-up effects in Section 6.

¹⁸In settings where it seems reasonable that $v_\theta \perp \theta$ or $\kappa_\theta \perp \theta$, models from Finkelstein and Notowidigdo (2019); Raffkin et al. (2023) should be used.

3. CONTEXT AND DATA

3.1. Institutional Context.

3.1.1. *Social Assistance in the Netherlands.* In the Netherlands, social assistance, or *algemene bijstand*, is a non-contributory social safety net program. It is intended for individuals who do not have enough income or assets to subsist, and who do not qualify for any other benefit. Over the period of this study, around 450,000 people claim benefits each year. This translates to around 4.5% of the general population and is more than the number of people on disability and unemployment insurance. [Figure B.1](#) shows the evolution of caseload from 2005 to 2021.

Eligibility: Eligibility rules are determined at the national level. The benefits are means-tested: income and assets must be below a threshold in order to be entitled. The income threshold is 100% of the full-time national minimum wage for couples, and 70% for singles. The threshold depends on household composition. Income includes not just labour income, but from capital and other benefits.

Additionally, eligibility requires being at least 18 years old and Dutch citizenship or residing lawfully in the Netherlands, not in prison or a detention center. Mental health does not directly affect eligibility.

Application: Applicants must submit information to verify eligibility (e.g. residency proof, income / bank statements etc) as well as potentially go to the municipal office for an interview. The municipality legally must make a decision within 8 weeks of application.

Receipt: If accepted, income is topped-up to the eligibility threshold - i.e. there is a 100% marginal tax rate.¹⁹ The national minimum wage, and couples' threshold, is around €16.5k per year during the observation period. Often, people earn some income - on average, benefits paid equal around €12.7k per year. Conditional on receipt, people stay on social assistance for around 5 years - there is no time-limit to take-up. Municipalities

¹⁹Basic income experiments have been trialled in some municipalities, where some treatment arms reduce/remove obligations and other treatment arms reduce the 100% claw-back of benefits ([Verlaet and Zulkarnain, 2022](#)). Strict obligations are rationalised by wanting to incentivise activation and eventual transitioning out to paid work in the face of the 100% marginal tax rate.

can grant additional benefits, such as housing, health insurance and children subsidies. In this paper, I focus on the take-up of the general welfare benefit.²⁰

Obligations: Social assistance is a workfare program: conditional on take-up, recipients must comply with several obligations. These include keeping all information up-to-date and work re-integration.²¹ Single parents with young children and people with full and permanent incapacity to work can apply for an exemption from these obligations. In the event of non-compliance, municipalities can impose sanctions or (temporarily) reduce benefits. Exclusion from assistance is an uncommon, extreme outcome.

3.1.2. *Healthcare in the Netherlands.* The Netherlands has a mandated and subsidised private health insurance system. GPs are the first port-of-call for mental health issues, and can prescribe medications or refer to specialized care. In the general population, around 10% of people are dispensed with psychopharmacological medications each year. Access to mental healthcare appears to be roughly equalised by income (Kolstad et al., 2024), although quality of care may differ (Lopes et al., 2023).

3.1.3. *Disability Insurance in the Netherlands.* One potential concern about my analysis is that perhaps it's not social assistance people with poor mental health should be receiving, but disability insurance. However, disability benefits count towards eligibility for social assistance. Insofar as people receive full disability benefits (e.g. people with severe mental disorders), they have income above the social minimum, are ineligible for social assistance and do not appear in my main analysis. Moreover, disability insurance is a contributory program replacing past earnings after work-limiting health shocks. Many people receiving social assistance do not have prior work history, so are ineligible for disability benefits. In sum, those with moderately poor mental health are in the target population.

²⁰This is a reasonable simplification because the take-up of these additional benefits is uncorrelated with receipt of social assistance, after controlling for income and wealth (Berkhout et al., 2019). Furthermore, these subsidies are phased-out according to different schedules to social assistance.

²¹Full list of obligations can be found in Ministerie van SZW (2015). They include acceptance of work or voluntary activities (i.e. "participate"), wearing the correct clothing doing so, being prepared to travel a distance with a total travel time of 3 hours per day to find work, keeping all eligibility and benefit-level information up-to-date, complying with information requests and even home-visits, being willing to relocate municipality, achieving a good command of the Dutch language and acquiring and retaining knowledge and skills necessary for acquiring wealth.

3.2. **Data.** In order to quantify the nature of selection of SA recipients with respect to mental health, I use administrative data from the population of the Netherlands (≈ 17 million people) accessed via CBS, the Statistics Agency of the Netherlands. The data contain information on socio-economic demographics determining eligibility for social assistance, rich characteristics on social assistance receipt and comprehensive information about mental health.

3.2.1. *Socio-economic information:* I create a new dataset containing eligibility for social assistance in the years 2011-2020 for all working-age individuals in the Netherlands. To do so, I extend the work of [Inspectie SZW \(2021\)](#) to calculate eligibility by merging detailed information on socio-economic information, including income, wealth, household composition and size, work status, education and other demographics, following the rules set out by law ([Ministerie van SZW, 2015](#)). These data are yearly, and so the measure reflects eligibility on average each year.²² The main analysis sample is from 2011 to 2020 because I observe all eligibility determinants in this period. I focus on working-age individuals throughout the study - age 27-65.²³ Among this population, around 10% of people are eligible for social assistance each year. [Table B.2](#) shows summary statistics about the socio-economic demographic variables, for the general population and for the eligible.

The administrative data show receipt of social assistance (among other benefits) for each person in each month, as well as benefits received, which household-composition-dependent threshold has been applied, any income earned, exemptions and sanctions. I use these data to calculate the take-up rate of social assistance - defined as $\mathbb{P}[\text{Take-up SA}|\text{Eligible}]$. Over the study period, the take-up-rate is around 60%, in line with [Inspectie SZW \(2021\)](#). I find $\mathbb{P}[\text{Take-up SA}|\text{Ineligible}] = 1\%$, suggesting low measurement-error.

3.2.2. *Mental health information:* Finally, the data contain three classes of mental health measures: take-up of mental healthcare (mental healthcare expenditures and dispensations of psychotropic medications by ATC4-code), extreme outcomes (hospitalizations with ICD-10 codes corresponding to mental health disorders, and deaths by intentional

²²I also calculate eligibility monthly for people who work - as the data contain monthly income information for employees. I use this for the regression kink design in [Section 6](#).

²³As in [Inspectie SZW \(2021\)](#), eligibility for students and people above pension-age is noisier and so these groups are excluded.

self-harm–suicides), and surveyed psychological distress (Kessler’s 10), loneliness and perceived control over own life (in a linked survey for 400k people in 2012 and 2016).

Figure 1 shows the prevalence of poor mental health in the Netherlands, and how this varies when focusing on the general population, those eligible for social assistance and recipients. The figure shows that the eligible are at least $2.5\times$ more likely to suffer with poor mental health than the general population. Whereas, social assistance recipients seem to have similar mental health to the eligible population.

This suggests that there does not seem to be substantial self-targeting. Otherwise, the more vulnerable group would be over-represented among the recipients. It would appear then that those with mental disorders face additional challenges accessing benefits.

3.3. Key Analysis Variables. In the rest of the paper, I empirically analyse the take-up of social assistance heterogeneously by mental health. Throughout, I define take-up as $SA_{it} = \mathbb{1}\{i \text{ receives SA in period } t\}$. For almost all results, this will refer to a stock. How should we measure poor mental health? I define Poor $MH_{it} = \mathbb{1}\{i \text{ dispensed psychotropic medications in year } t\}$.

In a related paper, we show that this is an accurate proxy for poor mental health status (Kolstad et al., 2024). In the Netherlands, usage of mental healthcare is strongly positively correlated with subjective psychological distress, and the relationship between the two does *not* depend on income (Kolstad et al., 2024). Prescriptions are done by GPs, who are the first access point to healthcare. In general, access to healthcare in the Netherlands is excellent, and people often still receive care even if they default on their premia (Roos et al., 2021). Indeed, 0.4% of *poor* households report unmet medical needs in the Netherlands, relative to 8.5% of *all* households in the US (Danesh et al., 2024).

Of course, even in the Netherlands there will be some non-take-up of mental healthcare by people with truly poor mental health. Therefore, throughout the empirical analysis I verify that all findings about mental health measured by dispensations of psychotropic drugs are consistent when mental health is measured in the survey.

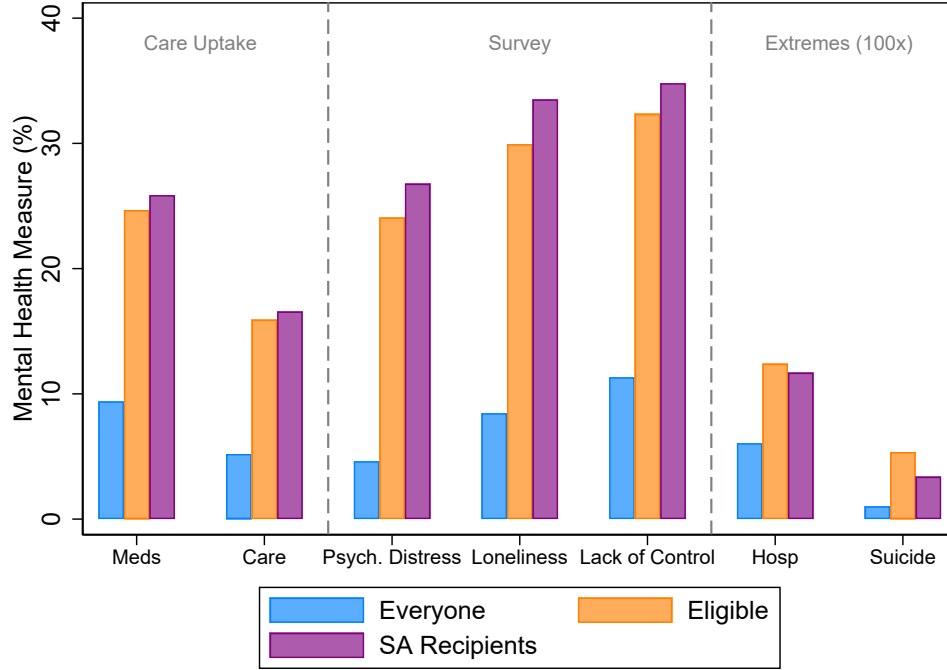

FIGURE 1. Prevalence of poor mental health in the Netherlands. This graph shows raw means of the seven mental health measures, across three different populations. All measures are in terms of percentages and are probabilities of the following: dispensed psychotropic medications, > 0 mental healthcare spending, surveyed severe psychological distress, surveyed severe loneliness, surveyed severe perceived lack of control over own life, hospitalisation due to a mental health condition, suicide. For the last two (extreme) outcomes, the probabilities are artificially inflated by 100x. The three populations are: everyone in the data, those eligible for social assistance, and the social assistance recipients, from 2011-2020 in each case.

4. AVERAGE TAKE-UP LEVELS

Average levels of the take-up of social assistance by mental health are useful descriptors to examine targeting and important inputs to identification of need and cost.

First, in terms of raw levels, figure [Figure 2](#) shows the baseline probability of being eligible for social assistance by mental health, measured by psychotropic drug dispensation, as well as the take-up levels conditional on eligibility. People with poor mental health are three times more likely to be eligible, but conditional on eligibility seem to take-up around the same rate as those with good mental health.

FIGURE 2. $\mathbb{P}[\text{Eligible}]$ and $\mathbb{P}[SA|\text{Eligible}]$, compared for people with poor mental health (dispensed psychopharma in year previously) vs good mental health (not). Underlying population: 2011-2020 in each case.

4.1. **Design.** Do people with poor mental health take-up social assistance more or less than people with good mental health, conditional on eligibility and income (and other observables)? This is **Step 1** in the three-step identification from [Section 2.3.1](#).

For each individual i and year t , define $SA_{it} = \mathbb{1}\{i \text{ receives SA in year } t\}$. $\text{Poor MH}_{it} = \mathbb{1}\{i \text{ dispensed psychopharma. in year } t\}$. [Equation \(4.1\)](#) represents a *correlation test* measuring the overall extent of selection, similar to [Rafkin et al. \(2023\)](#).²⁴

$$SA_{it} = \beta \cdot \text{Poor MH}_{it-1} + X'_{it-1}\theta + \varepsilon_{it} \quad (4.1)$$

X_{it} are flexible controls of income,²⁵ wealth, education, hh composition, work status, work sector and year, age, gender and municipality fixed effects. ε_{it} is an idiosyncratic error term. β measures the selection of social assistance recipients with respect to mental health and is the coefficient of interest.

²⁴Throughout, I use a linear-probability model, but the results are not substantially different using logit or probit.

²⁵I include household standardised income percentile (moving average $t - 4 \rightarrow t - 2$) fixed effects.

Importantly, I estimate the correlation test on the *eligible* population. Higher overall take-up rates by a group could come from higher probability of being eligible, or more frequent receipt conditional on eligibility. I focus on the latter in this paper because non-take-up by ineligible individuals is not attributable to the main forces of interest - need and ordeal costs.²⁶

4.2. Results. Table 1 shows the main results using $\text{Poor MH}_{it} = \mathbb{1}\{i \text{ dispensed psychopharma. in year } t\}$. Aligned with Figures 1 and 2, I find that people with poor mental health take-up social assistance only slightly more than those with good mental health. The table shows estimates of β , for seven specifications of increasing saturation.

Throughout, we see that those with poor mental health have similar take-up rates to those without. Once we control for year, age and gender fixed effects, the difference between good and poor mental health ranges from -1 to +1 p.p. depending on the controls. Most estimates are statistically significant, but all are economically small. Column 5 presents the full specification and shows that people with poor mental health receive social assistance $< 1\%$ more than people with good mental health, all-else fixed.

The addition of two specific controls explains a large share of the variation. Adding lagged controls for income increases the R^2 from 0.05 to 0.16. This is intuitive - people with poor mental health have vastly different incomes to those with good mental health, and income is a key confounder as it determines benefit-level. Second, adding lagged controls for work-status (including lagged social assistance receipt) increases the R^2 from 0.16 to 0.64. $\hat{\theta}_{SA_{t-2}=1} = 42.35$. Therefore, social assistance take-up is strongly auto-correlated.

The increase in the point estimate when adding lagged work-status as a control suggests that social assistance improves mental health because it indicates that part of the initial negative association between social assistance receipt and mental health is due to individuals who did not use social assistance in the past (and continue not to use it now) having poor mental health. Once you control for past work status, the analysis shows that among individuals with similar social assistance histories, those with poorer mental health are more likely to use assistance now. This shift suggests that social assistance may help alleviate some mental health challenges.

²⁶Indeed, [Mulwijk-Vriend et al. \(2019\)](#) show that $\hat{\beta}$ is positive for the overall population, but of course, this could be due to people with poor mental health being more likely to be eligible.

| | (1) | (2) | (3) | (4) | (5) | (6) | (7) |
|---|---------------------|------------------|--------------------|---------------------|---------------------|---------------------|----------------------|
| $\hat{\beta}$: Receipt of SA poor vs good MH (p.p.) | 3.072*** (0.810) | 0.491 (0.699) | -0.819* (0.362) | 1.429*** (0.095) | 0.540*** (0.071) | 1.984*** (0.065) | 0.911*** (0.0498) |

Standard errors in parentheses

* $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$

TABLE 1. Results of a regression of receipt of social assistance on mental health status (measured by dispensation of psychotropic meds). First column shows the results with no controls. Second column shows results adding year, age and gender fixed effects. Third column shows results adding lagged income controls. Fourth column shows results adding lagged hh composition, education, municipality, wealth and work-status controls. Fifth column shows results adding sector, physical health and benefits schedule controls. Sixth column shows results with individual fixed effects only (no controls). Seventh column shows results with individual fixed effects and all controls. The sample contains the calculated eligible for SA in 2011-2020. Standard-errors are clustered at the municipality-level.

How does $\hat{\beta}$ compare to the coefficients on other covariates, $\hat{\theta}$? The income percentile fixed effects range from 20 to -20, age fixed effects from 0 to 10 and municipality fixed effects from -15 to 5. This reinforces the idea that $\hat{\beta}$ is economically small.

Figure 3 presents the results of the correlation test varying the measure of poor mental health. $\hat{\beta}$ are plotted for each mental health status variable: $\mathbb{1}\{\text{dispensed of psychotropic meds}\}$, $\mathbb{1}\{\text{positive mental healthcare costs}\}$, $\mathbb{1}\{\text{Hospitalized for a mental health condition}\}$, and surveyed $\mathbb{1}\{\text{Severe psychological distress}\}$, $\mathbb{1}\{\text{Severe lack of control over own life}\}$, and $\mathbb{1}\{\text{Severe loneliness}\}$, relative to average take-up amongst those with good mental health. Qualitatively, these estimates are broadly consistent with each other and show a small positive difference in rate of receipt by people with poor mental health vs people with good mental health.

FIGURE 3. Results of a regression of take-up of social assistance on mental health status (measured by psychopharma prescription, log mental healthcare costs, being hospitalized for a mental health condition and three surveyed measures of subjective mental health). Lagged Controls: income, wealth, education, work status, hh composition and municipality, year, age, sector FEs, physical health and benefits schedule. The sample contains the calculated eligible for SA in 2011-2020. Standard-errors are clustered at the municipality-level.

Of course, there is a broad spectrum of different mental disorders. Using psychotropic drug dispensations to measure poor mental health provides a practical approach to distinguish these differences. Figure 4 shows coefficients from a regression of SA receipt on dummies for *type* of psychotropic drug dispensed, and all controls. People using ADHD medication, hypnotics / sedatives and anxiolytics are no more likely to receive social assistance than those not using any psychotropic medications. Anti-depressant dispensation is associated with a higher rate-of-receipt, whereas anti-psychotic dispensation is associated with a *lower* rate-of-receipt.

FIGURE 4. Results of a regression of take-up of social assistance on psychopharmacology dispensation fixed effects (by type: ADHD medications, anti-depressants, hypnotics/sedatives, anti-anxiety medications and anti-psychotics). Lagged Controls: income, wealth, education, work status, hh composition and municipality, year, age, sector FEs, physical health and benefits schedule. In the plot, drugs are ranked by how much they predict suicide in the following year from ADHD (not predictive) to anti-psychotics (highly predictive). The sample contains the calculated eligible for SA in 2011-2020. Standard-errors are clustered at the municipality-level.

5. BARRIER SCREENING EFFECTS

Moving past average take-up levels, recall from [Section 2](#) that we need to identify take-up responses to changes in barriers to assistance to reveal how costly people with poor mental health find overcoming these barriers and thus start to examine targeting effectiveness.

I examine the effects of the Participation Act, a large reform to social assistance design in the Netherlands, which increase barriers to access. The policy was announced in 2014 (with significant public discourse - see [Figure C.1](#)) and implemented in January 2015. The reform was a response to rising caseloads following the Great Financial Crisis, and it cut municipal social assistance budgets from €1.4 billion in 2010 to around €500 million by 2018 ([Heekelaar, 2021](#)). The Participation Act intensified obligations for recipients and incentivized municipalities to restrict inflow through (threat of) sanctions ([SCP, 2019](#); [van der Veen, 2019](#)).²⁷

5.1. Identification. I exploit the Participation Act to estimate the heterogeneous take-up response to a change in barriers by baseline mental health. Practically, the specification, [Equation \(5.1\)](#), is a standard Difference-in-Difference design with people poor mental health as the treatment group. The interpretation of the treatment effects is the heterogeneous effect $\frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} - \frac{\partial \mathbb{P}[SA]_H}{\partial \Lambda}$. The identification assumption is that people with poor mental health's receipt would have evolved in parallel to those with good mental health.²⁸

$$SA_{it} = \alpha + \eta_i + \gamma_t + \delta_t \times \text{Poor MH}_i + X'_{it}\theta + \varepsilon_{it} \quad (5.1)$$

η_i and γ_t are individual and year fixed-effects respectively. X is a vector of time-varying controls including income, education and municipality, hh composition and sector fixed effects. δ_t for $t \geq 2014$ are the coefficients of interest and represent the heterogeneous treatment effect of the policy by baseline mental health. $\text{Poor MH}_i = 1\{i \text{ dispensed psychotropic drugs at some point in the pre-period (2011 - 2014)}\}$. Throughout, I cluster standard-errors at the level of municipality of residence in 2013.

²⁷For more details, see [Appendix C.1](#).

²⁸The formal parallel trends assumption is that the receipt of social assistance by those affected by the policy would have evolved in the same way as a (purely hypothetical) control group who did not experience the policy, for every level of baseline mental health ([de Chaisemartin and D'Haultfœuille, 2023](#); [Shahn, 2023](#)).

I estimate Equation (5.1) for eligible middle-aged couples (ages 45-65), for whom the policy represents a clean exogenous increase in barriers only. I focus on couples because the eligibility threshold for single parents was cut in 2015, incentivising reclassification as single households. The take-up of social assistance pre/post 2015 by younger individuals is contaminated by inflow from a youth disability program (Wajong), where people with poor mental health are likely over-represented.²⁹ I focus on the eligible because the take-up responses for this group can be attributed to the change in barriers, not underlying changes in eligibility.³⁰ Sensitivity analyses confirm that the findings remain robust across various specifications and assumptions, as detailed in Section 5.5.

5.2. Main Results. Figure 5 shows the estimates $\hat{\delta}_t$ according to Equation (5.1). The groups are on parallel trends before the policy announcement, giving confidence to the identification assumption.³¹

The Participation Act disproportionately screens out people with poor mental health. The effect starts when the Act is announced, and then is especially pronounced in 2015. The overall difference-in-difference estimate of $\frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} - \frac{\partial \mathbb{P}[SA]_H}{\partial \Lambda} \approx -1\text{p.p.}$ This is comparable in magnitude (but opposite sign) to Finkelstein and Notowidigdo (2019) who estimate that barriers to SNAP in the US screen-out low-earnings potential types 2 percentage points *less* than high-types.

What do we learn from this through the lens of the theory? Section 4 suggests that take-up levels are roughly equalised on average. Therefore people with poor mental health have similar average value of benefits net of average cost of ordeals to people with good mental health. The barrier screening effects estimated show ordeals are more costly for those with poor mental health.³²

²⁹Figure C.6 shows the results when including adults aged 35-45. Although this group is more contaminated by Wajong entrants, the results are similar, suggesting the main estimates are not driven by Wajong entrants.

³⁰The effect holds also for those who are ‘always-eligible’ (eligible throughout 2011-2020), providing confidence that the main results are not driven by eligibility churn.

³¹Note: as the policy happens in the aftermath of the GFC, I expect $M \ll 1$ in the framework of Rambachan and Roth (2023). In this case, statistically insignificant pre-trends are meaningful.

³²The idea is that Step 1 shows the likelihood of being marginal is similar across types. Therefore, large heterogeneous barrier screening effects are informative of differences in cost.

FIGURE 5. Estimates $\hat{\delta}_t$ from Equation (5.1) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. The analysis population is eligible middle-age couples and poor mental health is defined by prescription of psychopharma in pre-period. Controls include individual fixed effects, income, education and municipality, hh composition and sector fixed effects. The TWFE estimate $\hat{\delta}$ in the regression $SA_{it} = \alpha + \eta_i + \gamma_t + \delta \cdot \mathbb{1}\{t \geq 2014\} \times \text{Poor MH}_i + X'_{it}\theta + \varepsilon_{it}$ is also shown. Standard-errors are clustered at the level of municipality of residence in 2013.

5.3. **Mechanism.** Figure 6 shows the effects on inflow and outflow. Outflow is not mechanically zero, the estimates are just tiny and have tight confidence intervals. This shows that the main results comes exclusively from a deterrence of inflow, aligning with Cook and East (2024) who suggest work requirements can screen-out individuals at the extensive margin. The disproportionate reduction in inflow for people with poor mental health (1p.p.) is around 10% of the baseline control mean (see Figure C.2).

The reduction of inflow suggests people with poor mental health are deterred by increased obligations and also from more unpleasant interactions with the municipality, given incentives to reduce caseload. Qualitative evidence from (Ministerie van SZW, 2022) supports the latter mechanism. The authors state that beneficiaries experience a

FIGURE 6. Estimates $\hat{\delta}_t$ from Equation (5.1) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. Here, I split by inflow (receipt conditional on being ineligible last period), and drop-out (non-receipt conditional on receipt last period). The analysis population is eligible middle-age couples and poor mental health is defined by prescription of psychopharma in pre-period. Controls include individual fixed effects, income, education and municipality, hh composition and sector fixed effects. The TWFE estimate $\hat{\delta}$ in the regression $SA_{it} = \alpha + \eta_i + \gamma_t + \delta \cdot 1\{t \geq 2014\} \times \text{Poor MH}_i + X'_{it}\theta + \varepsilon_{it}$ is also shown. Standard-errors are clustered at the level of municipality of residence in 2013.

“feeling of shame” and highlight a “negative tone” from the municipality where “small event[s] can have major consequences”. This creates “mutual distrust” and “fear” which creates a “barrier to applying for assistance, even when the need is great”.³³ Lack of out-flow corroborates SCP (2019) who find no effect of the Participation Act on transition into paid work.

³³Translated from page 8 of Ministerie van SZW (2022). See Appendix C.1 for full quote.

5.4. Different Mental Health Measures. How do the results compare when mental health is measured differently or across different disorders? [Figure 7](#) shows that the Participation Act screens-out those using anti-psychotics twice as much as those using anti-depressants. [Figure 8](#) shows that the barrier screening effects are more pronounced when poor mental health is measured by surveyed severe psychological distress. This likely reflects the fact that the main estimates are a lower-bound since some mental disorders are not diagnosed. Taking these results together suggests that severity of mental disorders—rather than simply their presence—exacerbates the dis-utility from ordeals.

FIGURE 7. Estimates $\hat{\delta}_t$ from [Equation \(5.1\)](#) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. Here, Poor MH_i can now take 3 values: 0 (control), 1 (anti-depressants) or 2 (anti-psychotics). The analysis population is eligible middle-age couples and poor mental health is defined by prescription of psychopharma in pre-period. Controls include individual fixed effects, income, education and municipality, hh composition and sector fixed effects. I plot the estimate $\hat{\delta}_t^{\text{Dep.}}$ and $\hat{\delta}_t^{\text{Psycho.}}$. The TWFE estimate $\hat{\delta}^{\text{Dep.}}$ and $\hat{\delta}^{\text{Psycho.}}$ and in the regression $SA_{it} = \alpha + \eta_i + \gamma_t + \delta \cdot \mathbb{1}\{t \geq 2014\} \times \text{Poor MH}_i + X'_{it}\theta + \varepsilon_{it}$ is also shown. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE 8. Estimates $\hat{\delta}_t$ from Equation (5.1) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. Here, Poor MH_i is defined in 3 ways: dispensations of psychotropic drugs in pre-period, > 0 mental healthcare costs in pre-period, surveyed severe psychological distress in 2012. The analysis population is eligible middle-age couples. Controls include individual fixed effects, income, education and municipality, hh composition and sector fixed effects. I plot the estimate $\hat{\delta}_t^{\text{Dep.}}$ and $\hat{\delta}_t^{\text{Psycho.}}$. The TWFE estimate $\hat{\delta}_t^{\text{Dep.}}$ and $\hat{\delta}_t^{\text{Psycho.}}$ and in the regression $SA_{it} = \alpha + \eta_i + \gamma_t + \delta \cdot \mathbb{1}\{t \geq 2014\} \times \text{Poor } MH_i + X'_{it}\theta + \varepsilon_{it}$ is also shown. Standard-errors are clustered at the level of municipality of residence in 2013.

5.5. Robustness. The main results of Section 5.2 are robust to several threats to identification. First, the sample consists of couples eligible for social assistance each year, a population that changes over time due to eligibility churn from income fluctuations and the inflow of individuals with youth disabilities. This raises concerns that the main result might be driven by differential take-up rates among new entrants and exiters to eligibility. However, Figure C.3 shows that the results are consistent for the always-eligible population—couples who remain eligible throughout the sampling period, suggesting that the

main results are not driven by differential selection of the newly eligible.³⁴ The point estimates being smaller for the always-eligible is unsurprising: these people are less likely to be on the margin of take-up.

Appendix C presents a formal presentation of the sample-selection issue. Consequently Figure C.4, which shows that the estimates are virtually unchanged when removing all time-varying covariates, is further evidence that eligibility flows do not drive the results.

Secondly, there could be contemporaneous policy changes which affect the take-up of social assistance heterogeneously by mental health. One threat is a reform to the structuring of long-term care (WMO) (Kromhout et al., 2018). The remit of home support for people with mental health issues was changed to be under the remit of municipalities starting in 2015. Figure C.5 shows the WMO reform does not drive the results.

The main results are not driven by inflow from Wajong (an income-support program for those experiencing disability shocks before age 18), which merged into the Participation Act in 2015. My sample restricts to individuals above age 45 to conservatively exclude those who might have transitioned from Wajong to social assistance. The only way this group could contaminate the sample is if they experienced a disability shock at 18, did not take up Wajong, survived without income support until age 45, and then opted for social assistance. Figure C.6 shows that the estimates are unchanged when including adults aged 35-45, confirming that the age restriction effectively controls for the potential contamination.

Thirdly, the Participation Act could have affected people with poor and good mental health differently due to its differential implementation, particularly the change in how eligibility was calculated based on household composition. To control for this, I include flexible controls for household size, and Figure C.4 shows that this does not drive the results.

Fourth, a concern is that the observed heterogeneous treatment effects could be due to pre-existing differences in take-up rates, rather than baseline mental health. However, when splitting the poor mental health group into subgroups—moderate (anti-depressants and anti-anxiety) and severe (anti-psychotics)—we find that both groups' take-up rates

³⁴While this may seem like a stark restriction, 25% of the eligible are always-eligible.

diverge from the good mental health group after 2015. Prior to 2015, the severely poor mental health group had lower receipt levels to the good mental health group, supporting the hypothesis that mental health differentially affects responses to barriers, and not simply pre-policy take-up levels.

The groups are defined based on pre-period dispensations, so we might worry that the $\hat{\delta}$'s are capturing the effect of mental health treatment on social assistance receipt. However, [Figure C.7](#) shows that results are similar when defining poor mental health based on self-reported symptoms, not prescriptions, and are even stronger. Additionally, [Figure C.8](#) shows that people dispensed drugs exhibit significantly worse mental health both before and after dispensation, with scores consistently above the threshold for moderate mental illness. A related concern would be that the results could be capturing the long-term effects of a mental health shock. [Figure C.9](#) shows that even when mental health is defined after the policy, a drop in $\hat{\beta}$ at 2015 persists.³⁵

6. BENEFIT TAKE-UP EFFECTS

In the final empirical part of the paper, I estimate the take-up response to exogenous variation in benefits. This quantity is informative of need for social assistance by revealed-preference. I leverage quasi-experimental variation in the benefit-level coming from the kinked benefits schedule as a function of income, using a fuzzy regression kink design (RKD) as in [Card et al. \(2015\)](#). The statutory benefits schedule is displayed in [Figure 9](#).

Before diving into the details of identification, [Figure 10](#) shows non-parametric evidence of the behavioural response to a change in benefit level by poor vs good mental health. The figure indicates that people suffering from mental disorders take-up *more* in response to increasing benefit-levels than those with good mental health. I plot take-up within *monthly* income slice, which diverges starkly at the threshold for poor vs good mental health.³⁶

³⁵Taken together, these findings suggest that being prescribed psychopharma at any point is an indicator of mental health status, which remains significantly worse than the good mental health group throughout the study period.

³⁶Granular analysis is critical - hence the switch to monthly data. We can reconcile the findings in [Figure 10](#) with the small difference in average take-up levels estimated in [Section 4](#) by recognizing that the overall results are largely driven by the 75% of eligible individuals who do not work. The RKD, however, is a LATE capture effects locally around the eligibility threshold.

FIGURE 9. Benefits schedule as a function of income

People with income above the threshold take-up primarily due to measurement error: some sources of income do not count towards the eligibility threshold. Therefore, I need to calculate the income concept used to determine eligibility. This Y_{calc} differs from Y_{true} because (a) some income information (e.g. from other benefits) is only recorded yearly, yet eligibility determined monthly. Unemployment spells are imputed. (b) Y is aggregated to the family level. Recall that families are 1 or 2 adults (+ kids) who live together and share costs. Cost-sharing is unobservable / subject to case-worker discretion. Y_{true} is observed for the selected sample: social assistance recipients.

To minimise attenuation from measurement error, I focus on single employees.³⁷ The data contain monthly income information for employees and singles are immune from issues in step (b). The result of these restrictions is minimal measurement error: [Figure D.1](#) shows a histogram of $Y_{\text{true}} - Y_{\text{calc}}$ for the analysis population of the RKD. Y_{true} is of course negatively selected for recipients, so we expect the distribution to be left-skewed.

³⁷Details of the estimation are in [Appendix D](#). Around the threshold, couples are significantly mismeasured because I cannot observe which adults live together as part of a family and which don't. This does not drive the barrier screening effects. [Figure C.10](#) shows that the results remain the same when focusing on individuals away from the threshold. Unfortunately, this does mean that internal validity concerns restrict the samples differently for barrier screening and benefit take-up effects. This does not affect results about *relative* need and cost by mental health, as discussed in [Section 7](#).

FIGURE 10. Average rate of receipt within income slice in a large window of income either side of the eligibility threshold. Income in this plot is monthly. Poor mental health is defined as receiving psychopharma in the year previously. The sample contains single employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions.

Measurement error has significant mass around 0 and both mean and median are small (-29EUR, 7EUR respectively).

6.1. Identification.

6.1.1. *Theory.* [Figure 10](#) measures $\frac{d\mathbb{P}[SA]}{dy}$ for income y . In order to retrieve the take-up response $\frac{d\mathbb{P}[SA]}{dB}$, we need to re-scale by $1/\frac{dB}{dy}$. The statutory benefits schedule would imply $\frac{dB}{dy} = -1$ below threshold, and 0 above.

There is a challenge: municipalities can deviate from the policy formula through income exemptions - some or all of y is ignored when calculating B . [Appendix D.1](#) sets out my theoretical approach to impute the ex-ante benefits schedule (i.e. the expected benefits a potential applicant is eligible for conditional on their income) accounting for exemptions. [Figure D.3](#) shows the results.

The imputation process is not perfect: it measures the ex-ante benefits schedule with error. Let B^* be the imputed (mis-measured) version of B : $B^* \triangleq B + U_B$. As discussed above, Y is also measured with error: $Y^* \triangleq Y + U_Y$. Therefore, I use a fuzzy RKD specification (Card et al., 2015). Proposition D.1 shows that a fuzzy RKD estimates a weighted average of marginal effects of B on $\mathbb{P}[SA]$.

6.1.2. *Estimation.* I estimate a standard fuzzy RKD specification, using local linear regression. I use a Calonico et al. (2014) robust bandwidth of €80, estimated separately for people who are (/not) dispensed psychotropic drugs in the year previously (poor/good mental health, respectively). The IV estimate $\frac{\hat{\beta}_1}{\delta_1}$ measures $\frac{\partial \mathbb{P}[SA|Y=\bar{y}]}{\partial B}$. Standard-errors are clustered at the municipality level.³⁸

$$SA_{it} = \alpha + \beta_0 \cdot (y_{it}^* - \bar{y}_i) + \beta_1 \cdot \min\{y_{it}^* - \bar{y}_i, 0\} + \varepsilon_{it} \quad (\text{Reduced Form})$$

$$B_{it}^* = \gamma + \delta_0 \cdot (y_{it}^* - \bar{y}_i) + \delta_1 \cdot \min\{y_{it}^* - \bar{y}_i, 0\} + \varrho_{it} \quad (\text{First Stage})$$

Support for Identification Assumptions: The key identification assumption is that there is no manipulation of income around the threshold. Figure 11 and Figure D.6 shows no evidence for strategic income targeting around the eligibility threshold: McCrary (2008) tests with seventh-order polynomials show no statistically significant bunching. Although the threshold equals the full-time monthly minimum wage, the sample works much less than full-time (around 100 hours per month) and income used for eligibility does not only come from labour. Adjustment frictions are likely a key reason for lack-of-bunching (Kleven, 2016).

6.2. **Main Results.** First, I pool people with good and poor mental health together. Figure D.12 shows that employees react significantly to the quasi-experimental variation in benefit-level. I estimate $\hat{\beta}_1 = -0.0338$ which translates to take-up increasing by $\approx 3.4p.p.$ for a €100 increase in the benefit level.

³⁸See Appendix D.2 for more details.

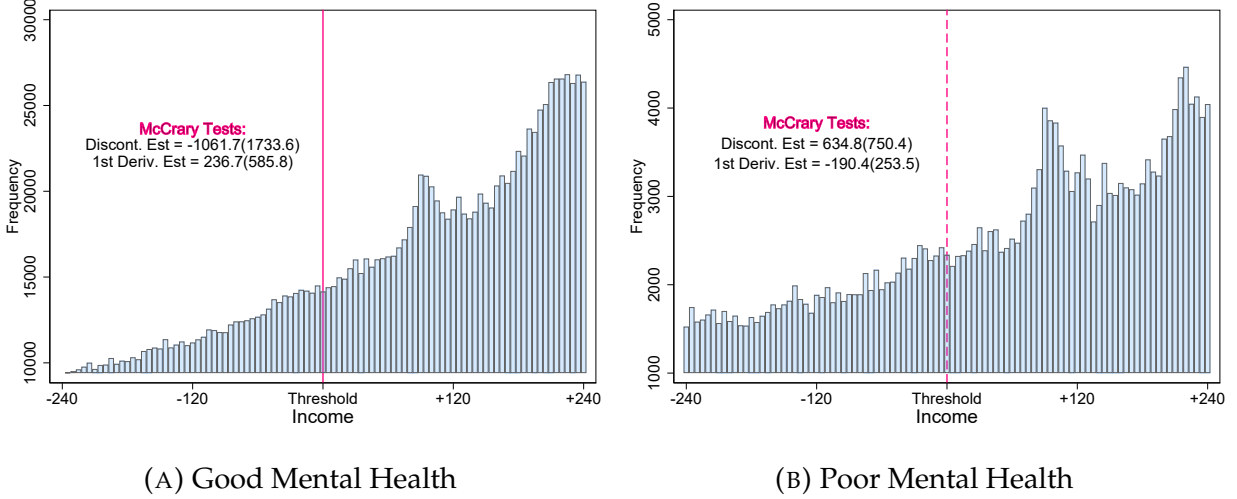

FIGURE 11. Density of income around the eligibility threshold. [McCrary \(2008\)](#) tests for discontinuity in levels and slopes around the threshold are shown. Income is monthly. Poor mental health is defined as receiving psychopharma in the year previously. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions.

People with mental disorders have a significantly larger take-up response to a change in benefits than those with good mental health. The results are shown in [Figure 12](#). I estimate $(\hat{\beta}_{1H}, \hat{\beta}_{1L}) = (0.0263, 0.0819)$. Measurement error is uncorrelated with mental health status - there is no statistically distinguishable difference in the slope above the threshold between good and poor mental health. Using the first stage in [Figure D.3](#) to re-scale the above reduced-form, we obtain IV estimates $\left[\frac{\hat{\beta}_1}{\hat{\delta}_1}\right]_{\text{Poor MH}} = 0.824$ and $\left[\frac{\hat{\beta}_1}{\hat{\delta}_1}\right]_{\text{Good MH}} = 0.280$.

As shown in [Figure D.8](#), such a stark difference between poor and good mental health is potentially due to selection on other observables. Including a rich set of controls dose not meaningfully change the findings. With controls, people with poor mental health to react twice as much to a change in benefits than those with good mental health. The full set of reduced-form and IV estimates (with and without controls) are contained in [Table D.1](#).

$$\frac{\partial \hat{\mathbb{P}}[SA|Y = \bar{y}]}{\partial B} = \begin{cases} 0.028 \text{ p.p.} & \text{for Good MH} \\ [0.27, 0.029] & \\ 0.065 \text{ p.p.} & \text{for Poor MH} \\ [0.037, 0.093] & \end{cases} \quad (6.1)$$

with an implied elasticity of 0.29, 0.76 respectively. These elasticities lie at the lower (/upper) end of range of previously estimated take-up elasticities of social insurance for

FIGURE 12. Average rate of receipt within income slice in a small window of income either side of the eligibility threshold. Income in this plot is monthly. Poor mental health is defined as receiving psychopharma in the year previously. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Regression lines are shown following [Section 6.1.2](#), as well as estimated change in slopes from the regression kink design. Standard-errors are clustered at the municipality level.

good (/poor) mental health respectively ([Krueger and Meyer, 2002](#); [McGarry, 1996](#)). The elasticity for poor mental health is more than double that of good mental health.

6.2.1. *Robustness.* I assess the credibility of the design with standard robustness analyses whose results are described in [Appendix D.6](#). [Figure D.7](#) shows no strong evidence of selection along observable characteristics around the kink. While there is statistically distinguishable selection for poor mental health, [Table D.1](#) shows that the addition of a rich set of covariates does not meaningfully affect the results. [Figure D.10](#) displays a permutation test ([Ganong and Jäger, 2018](#)), and shows no evidence for worrying non-linearities. [Figure D.10](#) and [Figure D.11](#) explore sensitivity of the results to different bandwidths.

Estimates are quite robust to lower bandwidths overall, and point estimates do not vary much in the heterogeneous case despite the confidence intervals overlapping with lower bandwidths.

6.3. Mechanisms. Why do people with poor mental health react more to a change in benefits, conditional on having the same income? Similarly to [Section 5](#), this larger sensitivity despite similar average take-up levels reflects higher need, i.e. a larger marginal value of income from social assistance. There are two main reasons why this might be the case.

First, cash transfers improve mental health ([Haushofer et al., 2020](#)). If people with poor mental health anticipate the protective effect of social assistance income on their mental health, it could cause them to value €1 more than people with good mental health and thus have a higher behavioural response.

However, I find no strong support for this mechanism in my setting. The reduced-form RKD induces exogenous variation in social assistance receipt, which I then regress future psychotropic drug dispensations on to estimate $\frac{\partial MH}{\partial SA}$. [Figure E.1](#) shows null results. This is perhaps not surprising - ([Solmi et al., 2022](#)) find that many mental illnesses start early in life - before people might enter my analysis sample. [Miller and Bairoliya \(2023\)](#); [Silver and Zhang \(2022\)](#) also do not find strong evidence that cash improves mental health.

Instead, I interpret these results through the psychology literature studying mental disorders. This literature often refers to the impairment of everyday functioning as a key mechanism in the difficulties this population face. Of course, the cognitive burden of mental illness, including effects on information processing, attention, memory and executive function can clearly hinder psycho-social functioning ([Kessler et al., 2003](#); [Evans et al., 2014](#)). Mental disorders can also affect everyday functioning through impaired emotion regulation - this can affect work, relationships and self-image ([Gross and Muñoz, 1995](#)).

The cognitive burden and emotion resilience tax imposed by mental disorders seemingly increases the difficulty handling common everyday stressors amongst the low-income population, thus increasing the value of support.³⁹ This idea aligns closely with Amartya

³⁹Indeed, people with poor mental health work less than those without, and limits on earnings capacity are indicative of higher marginal utility of benefits ([Deshpande and Lockwood, 2022](#)). An economic model of scarcity would resonate closely with this interpretation ([Mullainathan and Shafir, 2013](#)). Given limited mental resources, people with poor mental health will have a higher value of releasing resources through additional money compared to people with good mental health with the same initial income.

Sen’s “capabilities approach” (Sen, 1999, 2008); people with poor mental health need more income to get by.

Perhaps most interestingly, this higher need is estimated through revealed-preference. Not only do people with poor mental health need benefits more, they *think* that they need benefits more. This suggests that impaired functioning seems to dominate anhedonia and other psychological mechanisms lowering the perceived value of help. If anything, this is likely an under-estimate of true need given pessimism characterises depression, one of the most common mental disorders.⁴⁰

7. CALIBRATION OF WELFARE EFFECTS

In this section, I use the empirical results of Section 4, Section 5 and Section 6 to quantify need for benefits and cost of overcoming barriers, heterogeneously by mental health. These key primitives are important determinants to the effectiveness social assistance targeting using barriers. For example, I calculate the welfare effects derived in Proposition 2.1. To be clear, this is not the only way of measuring effectiveness. However *any* measure will need to trade-off the differential need for benefits by people with poor mental health against differential cost of overcoming barriers.

The sufficient statistics for these welfare effects are need (v'_θ), cost (κ'_θ), benefit take-up effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}\right)$ and barrier screening effects $\left(\frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda}\right)$.

7.1. Quantifying Sufficient Statistics. For the calibration, I assume $\theta \in \{L, H\}$: mental health is either poor or good. Throughout the empirical sections, I examine take-up conditional on eligibility. However, welfare-estimates should reflect the general population - for example because the government budget constraint should reflect the fact that the ineligible fund benefits for the recipients, and not the eligible non-takers. Appendix E.1 shows how to rescale take-up levels and responses estimated on the eligible to reflect the overall population.

7.1.1. Identifying Need and Cost. I employ the three-step identification method set out in Section 2.3.1. Appendix E.2 shows the full set of results of this calibration. First, Section 4

⁴⁰I return to bias in Section 7.

shows no meaningful difference in average take-up levels conditional on eligibility between poor and good mental health. Therefore, I apply the special case of **Step 1**, where equalized take-up levels implies equalized likelihood of being at the margin of take-up.

$$f_\varepsilon(v_L - \kappa_L) = f_\varepsilon(v_H - \kappa_H)$$

This result reflects the fact that *average* value net of cost seems to be roughly the same across mental health states. However, this does not necessarily pin down *marginal* value (need) - nor does it separate between need and cost.

First, I normalize $v'_H = 1$. As discussed in **Step 2**, this effectively scales need by the willingness-to-pay for €1 amongst people with good mental health. Moreover, it means that the benefit take-up response for people with good mental health measures $f_\varepsilon(v_H - \kappa_H)$. In [Section 6](#), I estimate $\frac{\partial \mathbb{P}[SA]_H}{\partial B} = f_\varepsilon(v_H - \kappa_H) = 0.00028$.

Need: Therefore, I apply **Step 2** and divide the benefit take-up response for people with poor mental health by the response for good mental health. The above implies $\frac{f_\varepsilon(v_L - \kappa_L)}{f_\varepsilon(v_H - \kappa_H)} = 1$. This, combined with $v'_H = 1$ shows that need for benefits for people with poor mental health is revealed as the *relative* benefit take-up response for this group. I estimate $\frac{\partial \mathbb{P}[SA]_L}{\partial B} = 0.00065$, which therefore implies $v'_L = 2.3$.

These estimates suggest that people with poor mental health have more than twice as high a marginal value of additional income (need) versus those with good mental health. The differences are not explained by differences in income, as the regression kink design estimates $\frac{\partial \mathbb{P}[SA]_\theta}{\partial B}$ conditional on income being equal to the eligibility threshold for both groups. This implies a strong redistributive motive towards people with poor mental health. Moreover, need is revealed from behaviour, suggesting that policy instruments to transfer income to those with poor mental health can be effective in practice.

The fact that people with poor mental health need money more, but take-up at the same rate as those with good mental health suggests they are inefficiently excluded from social assistance by barriers.

Cost: Finally, I use the difference-in-differences results of [Section 5](#) to calibrate $\kappa'_\theta(\Lambda)$. I use the raw descriptive drop in inflow for people with good mental health (see [Figure C.2](#)) to calibrate $\frac{\partial \mathbb{P}[SA]_H}{\partial \Lambda} = -0.014$. The main results of [Section 5](#) thus imply $\frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} = -0.023$.

I then apply **Step 3** of the identification method. Effectively, this combines these results with $f_\varepsilon(v_L - \kappa_L) = f_\varepsilon(v_H - \kappa_H) = 0.00028$, and implies that $\kappa'_H = 79$ and $\kappa'_L = 130$.

These quantities imply ordeals impose a 65% higher cost on those suffering from mental disorders relative to people with good mental health. This suggests that although governments have an incentive to redistribute money towards people with poor mental health, barriers to access are a costly way target.

7.1.2. The Role of Bias. What if individuals are biased? In this case, take-up responses reflect *perceived* need and cost, rather than true need or cost. On the cost side, the baseline model suggests substantial out-screening by barriers reveals large costs for the inframarginals, but in reality κ'_θ calibrated above can be thought of “as-if” costs of barriers (Goldin and Reck, 2022) which could differ from the truth. The costs are revealed by a policy which intensified obligations and increased unpleasant and stigmatising interactions with the municipality, who had a larger remit to impose sanctions. The policy disproportionately deters people with poor mental health from flowing-in to the benefit. Outflow does not change differentially.

These findings imply that perceived costs may overestimate actual costs. While the psychological impact of fear and shame, as discussed by Ministerie van SZW (2022), is likely non-negligible, the absence of differential outflow suggests that compliance costs from obligations may be over-stated. Thus, while barriers could actually target well, welfare outcomes hinge critically on the extent to which perceived costs diverge from true costs. I formalize this argument in the following section for the specific policy experiment studied, following Naik and Reck (2024).

On the need-side, pessimism is a common symptom of depression (Alloy and Ahrens, 1987), a common mental disorder. This suggests that the disproportionate perceived need for people with poor mental health is likely an *under-estimate*. Bias likely only increases the welfare effects of redistributing income to people with poor mental health.

7.2. Quantifying Welfare Effects. In this section, I calibrate the welfare effects of marginal changes in benefits and barriers as a function of the sufficient statistics. In the data, the prevalence of poor mental health conditional on eligibility is $\mu(L) = 0.25$. I set $\mathbb{P}[SA]_L = \mathbb{P}[SA]_H = 0.6$. I start from the baseline case of no social welfare preference

for poor mental health. The tax rate $\tau \approx 37\%$. This means that the heterogeneous monthly net fiscal externalities $FE_\theta = \tau(y^{SA=0} - y^{SA=1}) + (1 - \tau)B$ are, on average:

$$FE_L = 0.37 \times (\text{€}512.22 - \text{€}331.27) + (1 - 0.63) \times \text{€}972.22 = \text{€}679.45 \quad (7.1)$$

$$FE_H = 0.37 \times (\text{€}574.29 - \text{€}390.95) + (1 - 0.63) \times \text{€}916.29 = \text{€}645.09 \quad (7.2)$$

The fiscal externality of inducing someone with poor mental health to apply is larger than for good mental health. This is driven by people with poor mental health also receive more benefits than those with good mental health - mostly driven by the fact that they earn less when on social assistance. Here, the fact that $y_L^{SA=0} \approx y_H^{SA=0}$ comes from restricting to the eligible population. Intuitively, the change in policy induces the eligible to change their take-up rather than the ineligible. If we were to focus on the general population, $FE_H \gg FE_L$ as $y_L^{SA=0} \ll y_H^{SA=0}$.

7.2.1. MVPFs of Ordeals and Benefits. For the calibration, I recast welfare effects in terms of the Marginal Value of Public Funds (MVPF) (Hendren and Sprung-Keyser, 2020). This is defined as the willingness-to-pay for a policy change divided by the cost to the government's budget constraint. I estimate MVPFs for barrier and benefit changes.

In the baseline case, I follow Hendren and Sprung-Keyser (2020) and write the direct effects of policy changes in terms of each type's *own* willingness-to-pay. This money-metric social welfare function has the advantage of having interpretable units (€'s) for inter-personal utility comparisons. However, it does not capture any heterogeneity in marginal value of income across types - a factor which is crucial in this context. Proposition A.1 derives the formula for the MVPF of a change in barriers as:

$$MVPF_{d\Lambda} = \frac{\overbrace{- \int \mathbb{P}[SA]_\theta \cdot \frac{\kappa'_\theta(\Lambda)}{v'_\theta(B)} d\mu}^{\text{Direct Effect } < 0}}{\underbrace{\int FE_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda} d\mu}_{\text{Behavioral Revenue Effect } < 0}}$$

In the numerator, the direct costs of ordeals are rescaled by need so that they are measured in €'s. I estimate these quantities on the eligible population but aim to extrapolate to the general population, as shown in [Proposition E.1](#). For the numerator, this requires integrating against the conditional density of mental health for the eligible. For the denominator, we rescale the eligible take-up response by a constant for each θ , representing “effective eligibility.” The intuition is that we must adjust for baseline incomplete take-up and the fact that some ineligible individuals may be on the margin of take-up, as they could be just indifferent between earning slightly above the threshold or below it to qualify for social assistance.

$$\begin{aligned}
 MVPF_{d\Lambda} &= \frac{-0.6 \times \frac{130}{2.3} \times 0.25 - 0.6 \times \frac{79}{1} \times 0.75}{679.45 \times 0.25 \times (-0.023) \times \underbrace{\frac{1}{1 - 0.6 \times 0.907}}_{\text{Effective Eligibility}_L} + 645.09 \times 0.75 \times (-0.014) \times \underbrace{\frac{1}{1 - 0.6 \times 0.954}}_{\text{Effective Eligibility}_H}} \\
 &= 1.88
 \end{aligned}$$

An $MVPF_{d\Lambda}$ of 1.88 means that ordeals impose a direct cost of €1.88 on infra-marginals for every €1 saved by the government through lower take-up. $MVPF_{d\Lambda} \gg 1$ suggests that $d\Lambda$ is a costly way to raise government revenue. Notice the *money-metric* barrier costs of people with poor mental health are €56.4, whereas €79 for good mental health. However, €1 is more than twice as valuable to the person struggling with a mental disorder - which means that the monetary cost does not reflect the much greater dis-utility imposed by ordeals on individuals with mental illness.

[Proposition A.1](#) derives the formula for the MVPF of a change in benefits as follows, again extrapolating from the eligible population. An $MVPF_{dB} < 1$ is to be expected since social assistance is a re-distributive program. It means means that beneficiaries gain 81 cents for every €1 spent raising the benefit level. The estimated value lies in the range surveyed by [Hendren and Sprung-Keyser \(2020\)](#).

$$\begin{aligned}
MVPF_{dB} &= \frac{\overbrace{\int \cdot \mathbb{P}[SA]_{\theta} d\mu}^{\text{Direct Effect } > 0}}{(1 - \tau) \cdot \underbrace{\int \mathbb{P}[SA]_{\theta} d\mu}_{\text{Mechanical Revenue Effect } > 0} + \underbrace{\int FE_{\theta} \cdot \frac{\partial \mathbb{P}[SA]_{\theta}}{\partial B} d\mu}_{\text{Behavioral Revenue Effect } > 0}} \\
MVPF_{dB} &= \frac{0.6 \times 0.25 + 0.6 \times 1 \times 0.75}{0.63 \times (0.6 \times 0.25 + 0.6 \times 0.73) + 679.45 \times 0.25 \times \frac{0.00065}{1-0.6 \times 0.907} + 645.09 \times 0.75 \times \frac{0.00028}{1-0.6 \times 0.954}} \\
&\approx 0.82
\end{aligned}$$

Comparing $MVPF_{d\Lambda}$ to $MVPF_{dB}$ suggests that reducing ordeals is a $2.1 \times$ more effective policy than increasing benefits.⁴¹ Interpreted through the budget-neutral policy shift in [Proposition 2.1](#), this suggests that the government would actually reduce benefit levels to finance a reduction in take-up barriers.

I find that people with poor mental health have twice the need than those with good mental health, but a 65% higher cost. Why, then, does reducing barriers dominate increasing benefits? The reason is that poor targeting through barriers actually *reduces* the effectiveness of increasing *benefits*. Social assistance is poorly targeted on average, since take-up is similar across mental health states. This makes dB *costly* as it redistributes to all infra-marginal individuals. If people with good mental health had a much lower take-up rate, $MVPF_{dB}$ would be higher.

7.2.2. The Role of Bias. Consider the case that individuals are biased, and perceive barrier costs to be larger than their true value. Namely, let a share ψ of the as-if cost revealed through take-up responses be a true cost, and $1 - \psi$ pure hassle costs (which affect behaviour and not welfare). In this model, take-up is too low relative to the private optimum. Therefore, the $MVPF_{d\Lambda}$ scales down the direct cost of barriers by a factor ψ , but also includes a negative behavioural welfare effect $\times (1 - \psi)$ since individuals are not privately-optimizing so the Envelope Theorem does not hold. $MVPF_{dB}$ now contains a

⁴¹Note that the social marginal utility of the beneficiaries of the two policies should be taken into account when comparing the $MVPF$'s ([Hendren, 2016](#)). In [Appendix E](#), I show that the social marginal utility of beneficiaries of dB is 1.36 and of $d\Lambda = 1.27$

new term in the numerator - namely an internality correction $\times(1 - \psi)$ as increasing benefits helps individuals take-up closer to their private optimum. [Appendix E](#) shows the formulae.

When we calibrate these using the sufficient statistics estimated above, we find that the government must be confident that less than 44% of the perceived costs are true welfare costs in order to reverse the $MVPF_{d\Lambda} > MVPF_{dB}$. Here, I take the approach of [Naik and Reck \(2024\)](#): if revealed preference does not hold, the government does not know how much behaviour reflects true welfare. However, policies still need to be set. In this case, it is optimal for the government to choose policies which are *robust* to normative ambiguity. The result states that reducing barriers being more effective than increasing benefits is robust as long as more than 44% of the as-if costs are normatively relevant. Similarly, as long as pessimism is weak enough such that perceived need is not below 44% of true need, barriers are more effective than benefits.

7.2.3. Relaxing other Assumptions. I conclude with a discussion of two key identification assumptions, how to relax them through the use of additional structure and the effect this has on welfare consequences. The two key modelling assumptions are (i) Take-up depends on an additive independent choice shock, (ii) $\mathbb{P}[\text{Marginal to Barrier Change}]_{\theta} = \mathbb{P}[\text{Marginal to Benefits Change}]_{\theta}$. For full details, see [Appendix E.3](#).

(i) Relaxing independence involves adopting models from [Rafkin et al. \(2023\)](#) or [Finkelstein and Notowidigdo \(2019\)](#) where $v'_{\theta}(B)$ is independent of θ conditional on income. These models do not fit my context appropriately because they would imply that people with poor mental health have an easier time overcoming barriers, and are substantially *less* pessimistic about the benefit level. Both of these results contradict psychological evidence ([Martin et al., 2023b](#); [Evans et al., 2014](#); [Alloy and Ahrens, 1987](#)).

(ii) Recall that for internal validity reasons, I focus on different subsamples in [Section 5](#) and [Section 6](#), calling into question the extent to which marginal take-up responses can be compared. Note however, that **Step 2** of the 3-step identification [Section 2.3.1](#) can be applied separately to the two policy designs. Therefore, the result that people with poor mental health have a relatively $2\times$ higher need and a relatively 65% higher cost does not rely on assumption (ii). This assumption is relevant for the comparison between

need and cost *within-individual*. I show in [Appendix E.3](#) that relaxing assumption (ii) through additional structure on the take-up equation suggests that $\mathbb{P}[\text{Marginal to Barrier Change}]_{\theta} < \mathbb{P}[\text{Marginal to Benefits Change}]_{\theta}$. This suggests that ordeal costs are a *lower-bound* and pushes further in favour of reducing barriers over increasing benefits.

8. CONCLUSION

This paper shows that people with poor mental health are high-need, yet inefficiently excluded from social assistance due to high cost of overcoming barriers. I use a theoretical framework to show how to disentangle need for benefits and cost of barriers using take-up levels and how take-up responds to changes in benefits and barriers. Empirically, I find that while people with poor mental health are three times more likely to be eligible for low-income benefits, conditional on eligibility, they take-up at around the same rate as those with good mental health. A policy which increases barriers disproportionately screens out those with poor mental health, while they also take-up more in response to a change in benefits. This is estimated using a regression kink design on the kinked benefits schedule as a function of income. Combining theory and empirics shows that reducing barriers is twice as effective as increasing benefits.

Future work: As mentioned in [Section 7](#), the policy recommendations depend on whether costs of overcoming barriers are true welfare costs, or just hassle costs which affect behaviour and not welfare. Therefore, in future work I plan to elicit behavioural biases for people with poor mental health and use this quantification to determine optimal policy.

Moreover, throughout I have assumed a static model where mental health is not directly affected by ordeals. This simplification could mean that my estimates of the welfare effect of a change in ordeals is underestimated because barriers likely worsen mental health directly ([Brewer et al., 2022](#)). In this context, mental health is unique, for example in comparison to income or education, because of its potential to respond to aspects of the take-up environment.

Due to these issues, work in progress calibrates a dynamic structural model of evolving mental health type affecting and responding to receipt of social assistance. Through this exercise, I aim to quantify the discrepancies between welfare effects under a static model

with those under a dynamic setup. For example, people with poor mental health are more likely to be screened out. If this directly worsens their mental health, there would be evidence of a psychological poverty trap ([Haushofer, 2019](#); [Ridley et al., 2020](#)) which could decrease welfare effects.

Finally, the theoretical framework described above is designed for analysing the targeting of social assistance, however can easily be applied to study the welfare consequences of people with poor mental health being screened out of other programs. One program of particular relevance is mental healthcare itself. There is evidence of forgoing mental health treatment by people with serious mental disorders. For example, [Cronin et al. \(2024\)](#) develop a discrete choice model which suggests that people with poor mental health could have increased psychological cost of talk therapy, despite needing it more, which could cause them to forgo. My framework can be applied to evaluate the welfare consequences of this, and determine whether those suffering from mental disorders take-up mental healthcare at the optimum rate. Work is underway along these lines.

APPENDIX A. THEORY APPENDIX

Let θ have a type-specific indirect utility functions: $u_\theta(c, y)$ is increasing in consumption c and decreasing in earned income y . Income depends on take-up but is fixed otherwise:⁴² let $y_\theta^{SA=1}$ refer to income earned if on social assistance and $y_\theta^{SA=0}$ if not. All income (including benefits) is taxed at marginal tax rate τ . Thus, $v_\theta(B)$ is given by:

$$v_\theta(B) \triangleq u_\theta((1 - \tau) \cdot [y_\theta^{SA=1} + B], y_\theta^{SA=1}) - u_\theta((1 - \tau) \cdot y_\theta^{SA=0}, y_\theta^{SA=0}) \quad (\text{A.1})$$

Thus, value is the net-utility gain from social assistance and comes from two main sources. First, if $y_\theta^{SA=0} \leq y_\theta^{SA=1} + B$, θ derives utility from the top-up in consumption $(1 - \tau)y_\theta^{SA=0} \rightarrow (1 - \tau) \cdot [y_\theta^{SA=1} + B]$. Second, if $y_\theta^{SA=1} < y_\theta^{SA=0}$, θ also derives value from a lowered cost of working when supported by social assistance. Importantly, heterogeneous value across types does not only come from different y_θ , the utility functions u_θ also differ.

Note that eligibility then is defined as $y \leq \bar{y}$ where $y = SA \cdot y_\theta^{SA=1} + (1 - SA) \cdot y_\theta^{SA=0}$.

Proof of Proposition 2.1. Social welfare is defined as follows.

$$W = \int \lambda_\theta \mathcal{U}_\theta d\mu$$

Using the chain rule: $\frac{dW}{d\Lambda} = \frac{\partial W}{\partial \Lambda} + \frac{\partial W}{\partial B} \cdot \frac{\partial B}{\partial \Lambda}$, and using the Leibniz rule to differentiate under the integral gives Equation (2.5). Here, the Envelope Theorem implies the behavioural welfare effect is 0. For example,

$$\begin{aligned} \frac{d\mathcal{U}_\theta}{d\Lambda} &= \frac{d}{d\Lambda} \int_{-\infty}^{\varepsilon_\theta^*} [v_\theta(B) - \kappa_\theta(\Lambda) - \varepsilon] dF(\varepsilon) \\ &= \frac{d\varepsilon_\theta^*}{d\Lambda} \cdot \underbrace{[v_\theta(B) - \kappa_\theta(\Lambda) - \varepsilon_\theta^*]}_{=0 \text{ by defn of } \varepsilon_\theta^*} + \int_{-\infty}^{\varepsilon_\theta^*} [-\kappa'_\theta(\Lambda)] dF(\varepsilon) \end{aligned}$$

⁴²The assumption of no labour supply responses follows Finkelstein and Notowidigdo (2019) and simplifies the theoretical analysis. In the Netherlands, social assistance tops income up to a social minimum. Therefore, conditional on receipt, income ≈ 0 for many people. This means that the decision in practice can be reasonably approximated to take-up SA (and earn low/no income) vs do not take-up SA (and earn income).

The above step is the Envelope Theorem at work.

$$= -\kappa'_\theta(\Lambda) \cdot F(\varepsilon_\theta^*)$$

Similarly, $\frac{d\mathcal{U}_\theta}{dB} = v'_\theta(B) \cdot F(\varepsilon_\theta^*)$. Therefore:

$$\frac{dW}{d\Lambda} = \int \lambda_\theta \mathbb{P}[SA]_\theta \left[v'_\theta(B) \cdot \frac{dB}{d\Lambda} - \kappa'_\theta(\Lambda) \right] d\mu$$

Let G be the government's budget. Budget neutrality implies $\frac{dG}{d\Lambda} = 0$. Using the chain and Leibniz rule again, and dropping θ subscripts:

$$\begin{aligned} \frac{dG}{d\Lambda} = \int & \left[\tau(y^{SA=0} - y^{SA=1}) + (1 - \tau) \cdot B \right] \cdot \frac{\partial \mathbb{P}[SA]}{\partial \Lambda} + \left[\tau(y^{SA=0} - y^{SA=1}) + (1 - \tau) \cdot B \right] \cdot \frac{\partial \mathbb{P}[SA]}{\partial B} \cdot \frac{dB}{d\Lambda} \\ & + (1 - \tau) \cdot \mathbb{P}[SA] \cdot \frac{dB}{d\Lambda} d\mu = 0 \end{aligned}$$

Rearranging gives [Equation \(2.6\)](#). □

A.1. MVPF Formulae. The MVPF measures the ratio of the direct welfare effect to beneficiaries of a policy, divided by the cost to the government. Direct welfare effects are written in the units of each types' willingness-to-pay. [Hendren and Sprung-Keyser \(2020\)](#) show that the composite policy increasing Λ (B adjusts) is social-welfare improving, if the gains from increasing spending on dB exceed the losses from reducing spending through an increase $d\Lambda$.

Let η_θ denote each individual's social marginal utility of income. Therefore, $\eta_\theta = \lambda_\theta \cdot v'_\theta$: social marginal utility is equal to social marginal welfare weight \times individual marginal utility of income. Let $WTP_\theta^P = \frac{d\mathcal{U}_\theta}{dP} \cdot \frac{1}{v'_\theta}$ be θ 's willingness-to-pay for a policy P : the direct welfare effect divided by the marginal utility of income.

Proposition A.1. ([Hendren and Sprung-Keyser, 2020](#)) Let $\bar{\eta}_P$ be the average social marginal utility of the beneficiaries a policy P :

$$\bar{\eta}_P = \int \eta_\theta \frac{WTP_\theta^P}{\int WTP_\theta^P d\mu} d\mu \tag{A.2}$$

The composite policy experiment of a budget-neutral increase in Λ financing an increase in B is good for welfare W iff:

$$\bar{\eta}_{dB} \cdot MVPF_{dB} > \bar{\eta}_{d\Lambda} \cdot MVPF_{d\Lambda} \quad (\text{A.3})$$

where:

$$\bar{\eta}_{dB} = \int \eta_{\theta} d\mu \quad (\text{A.4})$$

$$\bar{\eta}_{d\Lambda} = \int \eta_{\theta} \frac{\kappa'_{\theta}/v'_{\theta}}{\int \kappa'_{\theta}/v'_{\theta} d\mu} d\mu \quad (\text{A.5})$$

and the MVPF of an increase in ordeals is given by [Equation \(A.6\)](#).

$$MVPF_{d\Lambda} = \frac{\overbrace{- \int \lambda_{\theta} \cdot \mathbb{P}[SA]_{\theta} \cdot \frac{\kappa'_{\theta}(\Lambda)}{v'_{\theta}(B)} d\mu}^{\text{Direct Effect} < 0}}{\underbrace{\int FE_{\theta} \cdot \frac{\partial \mathbb{P}[SA]_{\theta}}{\partial \Lambda} d\mu}_{\text{Behavioral Revenue Effect} < 0}} \quad (\text{A.6})$$

and the MVPF of an increase in benefit level is given by [Equation \(A.7\)](#).

$$MVPF_{dB} = \frac{\overbrace{\int \lambda_{\theta} \cdot \mathbb{P}[SA]_{\theta} d\mu}^{\text{Direct Effect} > 0}}{\underbrace{(1 - \tau) \cdot \int \mathbb{P}[SA]_{\theta} d\mu}_{\text{Mechanical Revenue Effect} > 0} + \underbrace{\int FE_{\theta} \cdot \frac{\partial \mathbb{P}[SA]_{\theta}}{\partial B} d\mu}_{\text{Behavioral Revenue Effect} > 0}} \quad (\text{A.7})$$

The direct effect of an increase in ordeals $d\Lambda$ is that it imposes dis-utility on infra-marginal individuals κ'_{θ} . Written in terms of € cost, this is $\frac{\kappa'_{\theta}}{v'_{\theta}}$. Increasing barriers saves the government money through lower take-up, corresponding to the denominator. The direct effect of an increase in benefit level dB is that it transfers €1 of benefits to all infra-marginal individuals. The government has to pay for the mechanical extra program cost, as well as the new-entrants. See [Appendix E.1](#) for how to calculate these formulas when sufficient statistics are estimated on the eligible population.

Proof of Proposition A.1. From the proof of Proposition 2.1,

$$\frac{\partial W}{\partial \Lambda} = - \int \lambda_\theta \mathbb{P}[SA]_\theta \kappa'_\theta d\mu \quad (\text{A.8})$$

$$\frac{\partial W}{\partial B} = \int \lambda_\theta \mathbb{P}[SA]_\theta v'_\theta d\mu \quad (\text{A.9})$$

$$\frac{\partial G}{\partial \Lambda} = \int FE_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda} d\mu \quad (\text{A.10})$$

$$\frac{\partial G}{\partial B} = (1 - \tau) \int \mathbb{P}[SA]_\theta d\mu + \int FE \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial B} d\mu \quad (\text{A.11})$$

The first two equations follow by the Envelope theorem, as in the proof of Proposition 2.1. Dividing yields the MVPF formulas.

□

Proof of ??. $\mathbb{P}[SA]_L = \mathbb{P}[SA]_H$ and $\varepsilon \perp \theta$ implies $F_\varepsilon(v_L(B) - \kappa_L(\Lambda)) = F_\varepsilon(v_H(B) - \kappa_H(\Lambda)) \implies v_L(B) - \kappa_L(\Lambda) = v_H(B) - \kappa_H(\Lambda) \implies f_\varepsilon(v_L(B) - \kappa_L(\Lambda)) = f_\varepsilon(v_H(B) - \kappa_H(\Lambda))$.

Therefore, $\frac{\partial \mathbb{P}[SA]_L - \mathbb{P}[SA]_H}{\partial \Lambda} < 0 \implies \kappa'_L(\Lambda) > \kappa'_H(\Lambda)$. Under linearity $\kappa_\theta(\Lambda) = \kappa_\theta \cdot \Lambda$, this then implies $v_L(B) > v_H(B)$.

□

A.2. Identification. In this section, I set out how to identify the relationship between $f_\varepsilon(v_\theta - \kappa_\theta)$ across types using take-up levels and a first-order Taylor approximation. The key case is when $\mathbb{P}[SA]_\theta \neq \mathbb{P}[SA]_{\hat{\theta}}$. For argument's sake - suppose that we are considering two types $\theta = L, H$.

This proposition requires some additional structure:

Let indirect utility $u_\theta(c, y) = v_\theta \cdot c - \frac{n_\theta}{1+1/e} \cdot \left(\frac{y}{n_\theta}\right)^{1+1/e}$: quasi-linear utility with scaling factor v —denoting the marginal value of income—and isoelastic disutility of labour, as in e.g. Kleven (2016). Individuals then differ based on their value of money, and their ability n_θ . For simplicity, Frisch elasticities are the same across types. In this case, $y^{SA=0} = \arg \max u((1 - \tau)y, y) = n \cdot v \cdot (1 - \tau)^e$. Suppose also that $\kappa(\Lambda) = \kappa_1 \cdot \Lambda + \kappa_0$. Therefore,

$$SA = 1 \iff u((1 - \tau) \cdot (B + y^{SA=1}), y^{SA=1}) - \kappa \cdot \Lambda + \kappa_0 - \varepsilon \geq u((1 - \tau)y^{SA=0}, y^{SA=0}) \quad (\text{A.12})$$

Then:

Proposition A.2. Identification of $f_L \triangleq f_\varepsilon(v_L - \kappa_L)$ in terms of $f_H \triangleq f_\varepsilon(v_H - \kappa_H)$ is given by:

$$\mathbb{P}[SA]_L - \mathbb{P}[SA]_H \approx \left(\Psi \frac{\partial \mathbb{P}[SA]_L}{\partial B} + \Lambda \frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} \right) \cdot \left(\frac{f_L}{f_H} - 1 \right) \quad (\text{A.13})$$

$$\text{where } \Psi = B + y^{SA=1} - \frac{y^{SA=0}}{1+e} - \frac{(y^{SA=1})^{1+1/e}}{(y^{SA=0})^{1/e}(1+e)}.$$

Note that if the LHS = 0, the RHS will imply that $f_L = f_H$ as long as $\Psi \frac{\partial \mathbb{P}[SA]_L}{\partial B} \neq \Lambda \frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda}$.

Proof.

$$v(B) = u((1 - \tau) \cdot (B + y^{SA=1}, y^{SA=1}) - u((1 - \tau)y^{SA=0}, y^{SA=0}))$$

First, by Taylor's theorem:

$$\mathbb{P}[SA]_L - \mathbb{P}[SA]_H = F(v_L - \kappa_L) - F(v_H - \kappa_H) \approx [v_L - v_H - (\kappa_L - \kappa_H)] \cdot \underbrace{f(v_H - \kappa_H)}_{f_H}$$

We would like to approximate $v_L - v_H$ and $\kappa_L - \kappa_H$ using take-up responses to changes in B and Λ .

Given the structural assumptions, $v(B) = v \cdot (1 - \tau) \{B + y^{SA=1} - y^{SA=0}\} - \frac{n}{1+1/e} \cdot \left(\frac{y^{SA=1}}{n} \right)^{1+1/e} + \frac{n}{1+1/e} \cdot \left(\frac{y^{SA=0}}{n} \right)^{1+1/e}$. But since $y^{SA=0} = n \cdot v \cdot (1 - \tau)^e$, this means:

$$v(B) = v \cdot (1 - \tau) \cdot \underbrace{\left\{ B + y^{SA=1} - \frac{y^{SA=0}}{1+e} - \frac{(y^{SA=1})^{1+1/e}}{(y^{SA=0})^{1/e} 1+e} \right\}}_{\triangleq \Psi} \quad (\text{A.14})$$

Note that: $v'(B) = v \cdot (1 - \tau)$ in this setting. Finally, I assume $\kappa(\Lambda) = \kappa_1 \cdot \Lambda + \kappa_0$ where $\kappa_1 = \kappa'(\Lambda)$. To match the empirical application, assume income is fixed across types. Therefore:

$$\begin{aligned} F(v_L - \kappa_L) - F(v_H - \kappa_H) &\approx [(v'_L(B) - v'_H(B)) \cdot \Psi - (\kappa'_L(\Lambda) - \kappa'_H(\Lambda)) \cdot \Lambda - \Delta \kappa_0] \cdot f_H \\ &= \left(\frac{\partial \mathbb{P}[SA]_L}{\partial B} \cdot \frac{f_H}{f_L} - \frac{\partial \mathbb{P}[SA]_H}{\partial B} \right) \cdot \Psi \\ &\quad + \left(\frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} \cdot \frac{f_H}{f_L} - \frac{\partial \mathbb{P}[SA]_H}{\partial \Lambda} \right) \cdot \Lambda - \alpha \end{aligned}$$

by Equations (2.8) and (2.9) and where $\alpha = f_H \cdot \Delta \kappa_0$. Note that when the LHS = 0, we know that $f_L = f_H$. Therefore, $\alpha = \left(\frac{\partial \mathbb{P}[SA]_L}{\partial B} - \frac{\partial \mathbb{P}[SA]_H}{\partial B} \right) \cdot \Psi + \left(\frac{\partial \mathbb{P}[SA]_L}{\partial \Lambda} - \frac{\partial \mathbb{P}[SA]_H}{\partial \Lambda} \right) \cdot \Lambda$. Rearranging gives Equation (A.13).

□

APPENDIX B. CONTEXT AND DATA

This section contains summary statistics about the data - comparing the general population to those eligible for social assistance. Pseudocode for my calculation of eligibility is presented in [Appendix B.1](#)

FIGURE B.1. Take-up of SA (%) is plotted over time for 2005 - 2021. Both absolute caseload and inflow are shown. Two time periods are defined by an important policies: before/after the Participation Act of 2015 as discussed above.

| (Mental) Health Information | General Population (Mean, SD) | Eligible (Mean, SD) |
|-------------------------------------|-------------------------------|---------------------|
| General | | |
| All Care Spending (EUR) | 2,037.4 (7,181.0) | 3,711.6 (11,015.0) |
| Physical Chronic Conditions (count) | 0.67 (1.13) | 1.03 (1.44) |
| Mental Health | | |
| Mental Healthcare Spending (EUR) | 274.3 (3,237.2) | 1,055.9 (6,892.6) |
| Psychotropic Medication (%) | 10.3 (30.3) | 24.7 (43.1) |
| Anti-psychotics (%) | 2.1 (14.4) | 8.4 (27.7) |
| Anxiolytics (%) | 2.2 (14.7) | 8.0 (27.1) |
| Anti-depressants (%) | 7.6 (26.6) | 16.1 (36.7) |
| Hypnotics and Sedatives (%) | 1.2 (11.1) | 4.5 (20.7) |
| ADHD Medication (%) | 0.7 (8.5) | 1.7 (12.8) |
| Mental Health Hospitalizations (%) | 0.05 (2.1) | 0.12 (3.5) |
| Deaths by Suicide (%) | 0.01 (1.2) | 0.05 (2.3) |

TABLE B.1. Summary Statistics for General and Eligible Populations

B.1. Eligibility Pseudocode.

| Socio-economic Demographics | General Population | Eligible |
|--|---------------------------|---------------------|
| Gender (%) | | |
| Woman | 49.9 | 53.8 |
| Man | 50.1 | 46.2 |
| Education (%) | | |
| Primary School | 5.4 | 26.7 |
| High School | 31.8 | 46.8 |
| Bachelor's | 14.3 | 6.0 |
| Masters-PhD | 8.5 | 2.6 |
| Unknown | 40.1 | 17.9 |
| Main source of Income (%) | | |
| Employment or Civil Service Job | 63.2 | 8.9 |
| Director-shareholder | 2.2 | 0.1 |
| Self-employment | 9.9 | 4.6 |
| Other Job | 0.2 | 0.0 |
| Unemployment Insurance | 2.0 | 2.5 |
| Disability Insurance | 5.5 | 6.5 |
| Social Assistance | 4.3 | 55.3 |
| Other Benefits | 1.9 | 12.9 |
| Pension | 3.8 | 1.3 |
| Student Aid | 0.6 | 3.3 |
| Other (not active or without income) | 6.1 | 4.7 |
| Household Composition (%) | | |
| Single person household | 17.8 | 45.6 |
| Couple without children | 26.8 | 11.1 |
| Couple with children | 45.1 | 20.1 |
| Single parent | 6.4 | 19.6 |
| Couples and parents with flatmates | 2.1 | 1.9 |
| Other shared households | 1.0 | 1.6 |
| Other Information | | |
| Age | 46.4 (11.0) | 45.0 (11.3) |
| Foreign-born (%) | 16.4 (37.0) | 42.5 (49.4) |
| Household Std. Disposable Income (EUR) | 66,949.4 (73,978.0) | 13,125.2 (2,795.6) |
| Household Net Worth (EUR) | 169,760.0 (4,227,453.1) | -5,497.5 (85,933.0) |
| Contracted Hours (per year) | 1,509.7 (602.6) | 471.1 (451.0) |
| Eligible (%) | 6.6 (24.8) | 100.0 (0.0) |
| Receipt of Social Assistance (%) | 5.1 (21.9) | 60.0 (49.0) |

TABLE B.2. Summary Statistics for General and Eligible Populations

Algorithm 1 Eligibility Calculation

```
1: Procedure CalculateIncome(calculation_type)
2:   if (calculation_type == "Yearly")
3:     Income = income from work, assets & benefits.
4:     Deduct taxes & national insurance contributions
5:   else if (calculation_type == "Monthly")
6:     Gross Income = monthly employment income (spolis).
7:     Gross Income  $\mapsto$  Add yearly income from business, assets, sickness/disability
      benefits /12
8:     Gross Income  $\mapsto$  Add unemployment benefits over periods with no employment
      income
9:     Deductions = payroll taxes + national insurance contributions + employee insur-
      ance contributions
10:    Deductions  $\mapsto$  Add other taxes (not on bijstand income)
11:
12: Procedure DefineFamilies()
13:   Households = as in household income data (rinpersoonkern).
14:   Co-residents = people living at same address
15:   Families =  $\leq 2$  adult Co-Residents in same Household, plus children.
16:
17: Procedure CostSharing()
18:   Cost-sharers = adults
19:   Remove students (age 21-30) not receiving student grants
20:   Threshold = threshold ( # Cost-sharers in Family)
21:   Add norm-adjustment for all singles pre-2015.
22:
23: Procedure CheckEligibility()
24:   Set Eligible = "Yes" if Income  $\leq$  Threshold, wealth  $\leq$  wealth limit, and house value  $\leq$ 
      house limit.
25:   Set Eligible = "No" if age < 21 or striking or living outside NL or in institutional
      hh or {age 21-27 student not receiving student grants}
```

APPENDIX C. BARRIER SCREENING EFFECTS: ADDITIONAL MATERIAL

FIGURE C.1. Google Trends for *Participatiewet*, the Dutch translation of the “Participation Act” over time in the Netherlands.

C.1. Detail on the Participation Act. I argue that the Participation Act increased barriers to accessing social assistance. The policy intensified the obligations associated with receiving social assistance and incentivised municipalities to reduce caseload which they did via (threat of) sanctions.

SCP (2019), a report evaluating the Participation act, contains the results from a survey of 80 municipalities which asked representatives how often they impose obligations, and for each type of obligation how many impose these more after the introduction of the Participation Act. An overview of the results are shown in Table C.1.

Table C.1 shows that many municipalities say they intensified the various obligations. No surveyed municipality said that they imposed obligations less often. Indeed, van der Veen (2019) state that “the PA introduced a much stricter regime of entitlement conditions, involving mandatory participation in ‘re-integration’ activities [... and] introduced an important element of workfare, the so-called ‘quid-pro-quo’”.

| Obligation | Percent of Impose | Percent More Since PA15 |
|-----------------|-------------------|-------------------------|
| Language | 76.5 | 69.4 |
| Work | 93.8 | 26.3 |
| Accept Jobs | 95.1 | 19.5 |
| Register | 48.1 | 20.5 |
| Move | 13.6 | 54.5 |
| Commute 3 hours | 29.6 | 50.0 |
| Acquire skills | 75.3 | 24.6 |
| Clothes | 63.0 | 49.3 |
| Quid-pro-quo | 87.7 | 56.8 |

TABLE C.1. Percentage of municipalities surveyed who impose the full list of obligations (Column 2) and who impose obligations more often since the Participation Act (Column 3). The different obligations in-full are: achieving a good command of the Dutch language, work re-integration, register as a job seeker, being willing to relocate municipality, being prepared to travel a distance with a total travel time of 3 hours per day to find work, acquiring and retaining knowledge and skills necessary for acquiring wealth, wearing the correct clothing in work/volunteering, and quid-pro-quo unpaid voluntary work.

There are plans in the Netherlands to repeal the Participation Act. [Ministerie van SZW \(2022\)](#) makes the case for a “Participation Act in Balance”. The authors work with (former) social assistance recipients, municipalities and other experts to suggest that the obligations associated with the 2015 are too strict. They state:

“Applying for social assistance is experienced by various experts as complex, tedious and too long. A negative tone [by the municipality] is also mentioned, threatening action from the outset and a creating a sense of mutual distrust. At the same time, citizens experience a high degree of dependence on the government. A feeling of shame prevails that they have to make use of social assistance, even though in situations they simply cannot (temporarily) do otherwise. People definitely understand the need for monitoring and enforcement, but the way in which this is done now is drastic. A small event can have major consequences. People do not always feel heard or treated as an equal person. Fear also arises. This can create a barrier to applying for assistance, even when the need is great.”⁴³

⁴³Translated from page 8 of [Ministerie van SZW \(2022\)](#)

FIGURE C.2. Evolution of inflow of social assistance over time, split by people with poor mental health in the pre-period vs those with good mental health in this period. Raw means and respective 95% confidence intervals are shown. The introduction of the Participation Act in 2015 is shown by the red vertical line. Standard-errors are clustered at the level of municipality of residence in 2013.

C.2. Results. Formally, the sample-selection issue can be framed as follows. Let $\mathbf{e}_i = (e_{i1}, \dots, e_{iT})$ where $e_{it} \in \{0, 1\}$ denotes eligibility. Let \mathbb{X}_{it} be all explanatory variables (and \mathbf{X}_i similarly). Essentially, we only “observe” $(\mathbf{X}_{it}, SA_{it})$ for i, t such that $e_{it} = 1$ - i.e. only these observations are included in the regression. Wooldridge (2019) shows that the necessary identification assumption in this setting is given by Equation (C.1).

$$\mathbb{E}[\varepsilon_{it} | \mathbf{X}_i, \eta_i, \mathbf{e}_i] = 0 \quad (\text{C.1})$$

However, note that eligibility is a (non-linear) function of observables: $e_{it} \triangleq \phi(y_{it}, \bar{y}_i, \dots)$. Therefore, controlling for y_{it}, \bar{y}_i etc implies that selection is fully determined by observables. I.e. the standard assumption $\mathbb{E}[\varepsilon_{it} | \mathbf{X}_i, \eta_i] = 0$ is sufficient. In this case, it is particularly important to check that the time-varying controls are not driving the results.

FIGURE C.3. Estimates $\hat{\delta}_t$ from Equation (5.1) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. The analysis population is always-eligible middle-age couples and poor mental health is defined by prescription of psychopharma in 2012, 2013 or 2014. Controls include individual fixed effects, income, education and municipality, hh composition and sector fixed effects. The TWFE estimate $\hat{\delta}$ in the regression $SA_{it} = \alpha + \eta_i + \gamma_t + \delta \cdot \mathbb{1}\{t \geq 2014\} \times \text{Poor MH}_i + X'_{it}\theta + \varepsilon_{it}$ is also shown. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.4. Estimates $\hat{\delta}_t$ from Equation (5.1) showing the heterogeneous treatment effects of an increase in ordeals on rate-of-receipt by baseline mental health. The analysis population is eligible middle-age couples and poor mental health is defined by prescription of psychopharma in pre-period. $\hat{\delta}_t$ are shown for two specifications - one with no time-varying controls (only individual FEs), and one with all time-varying controls - individual fixed effects, income, education and municipality, hh composition and sector fixed effects. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.5. TWFE Event Study estimates, adding controls for receiving long-term-care adjustments from the municipality, receipt of Wajong, and exemptions to obligations. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.6. TWFE Event Study estimates for different age ranges. Standard-errors are clustered at the level of municipality of residence in 2013.

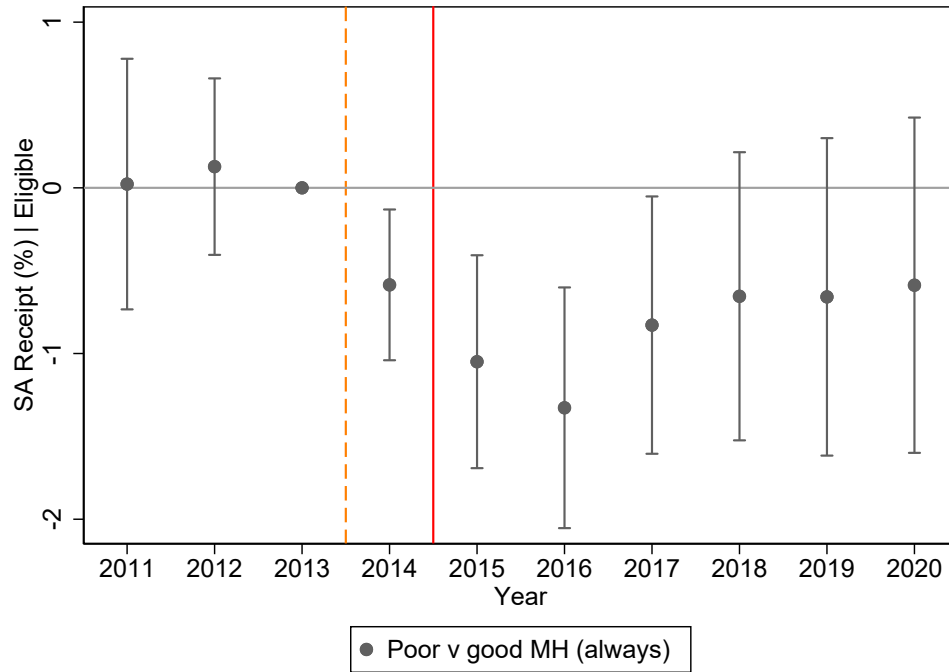

FIGURE C.7. $\hat{\delta}$ for the main specification, where Poor MH_{*i*}: dispensed psychopharma in every year 2011-2020, vs good mental health throughout. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.8. This plot shows the mean subjective mental health (measured by Kessler's 10 Psychological Distress) for two groups: one group is prescribed psychopharma for the first time in Event Time 0, the other group has no prescriptions for all event times $t \leq 0$. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.9. $\hat{\delta}$ for the main specification, changing the definition of Poor MH_i . The different definitions are $\text{Poor MH}_i = \mathbb{1}\{\text{Prescribed Psychopharma in year } y\}$, showing estimates for $y \in \{2012, \dots, 2017\}$. Standard-errors are clustered at the level of municipality of residence in 2013.

FIGURE C.10. $\hat{\delta}$ for the main specification for individuals with income below 90% of the eligibility threshold. $\text{Poor MH}_i = \mathbb{1}\{\text{Prescribed Psychopharma in pre-period}\}$. Standard-errors are clustered at the level of municipality of residence in 2013.

APPENDIX D. BENEFIT TAKE-UP EFFECTS: ADDITIONAL MATERIAL

This section contains additional material relating to the RKD estimation of the effect of changes in benefit level on SA receipt (heterogeneously by mental health).

FIGURE D.1. Histogram of $Y_{\text{true}} - Y_{\text{calc}}$ for the analysis population of the RKD.

D.1. **Theory.** Income is exempted “insofar as, in the judgment of the [municipality], it contributes to [their] employment opportunities” (Ministerie van SZW, 2015). Appendix D.3 contains some descriptive facts about income-exemptions. This complicates matters because now, B is no longer deterministic (it depends on case-worker leniency) and $\frac{dB}{dy} \neq 1$ necessarily. Let the true benefits schedule be denoted $B = b(Y, \nu)$ where ν captures noncompliance with policy formula due to exemptions.

To properly re-scale the reduced-form estimates, we need to know how B depends on Y ex-ante. However, there is selection into social assistance with respect to exemptions. This makes sense because applicants receive more money with an exemption vs without, holding income fixed. Figure D.2 shows that observed benefits conditional on receipt departs from the benefits schedule, particularly at and above the threshold. In this region,

applicants really only take-up social assistance if they receive an exemption. Selection on exemptions implies ex-post benefits received $\mathbb{E}[B|SA, Y = y]$ is not a good proxy for the ex-ante schedule $\mathbb{E}[B|Y = y]$.

I impute the benefits schedule using a theoretical approach.⁴⁴ I recover the ex-ante schedule from the ex-post schedule using Bayes-rule and average receipt. This re-scaling exercise explained in-depth in [Appendix D.3](#). While we may be worried about the endogeneity of using receipt in this calculation, I obtain similar results when I assume a less-flexible form for the probability of exemption - i.e. that it is constant w.r.t. y . In this case, the imputation does not depend on the full take-up function by income.

[Figure D.3](#) shows the results of the process to impute the ex-ante benefits schedule, heterogeneously by baseline mental health (measured by lagged psychopharma dispensations). People with poor mental health receive more exemptions than those without - presumably because they have larger costs of working and this incentivises the municipality promote re-integration more.

I use the generalized non-separable model of [Card et al. \(2015\)](#): receipt of SA is a function of benefit level B , income Y and error term ε : $\mathbb{P}[SA] = p(B, Y, \varepsilon)$. Let I_X be the support of random variable X which is potentially multi-dimensional, in which case represents a product space.

Proposition D.1. ([Card et al. \(2015\)](#)) *Under regularity, smooth effect of income, y , first stage and non-negligible population at the kink, smooth density, smooth probability of no measurement error and monotonicity:*

(a) $\mathbb{P}[\varepsilon \leq e, \nu \leq v | Y = y]$ continuously differentiable in y^* at $y^* = \bar{y} \forall (e, v) \in I_{\varepsilon, \nu}$.

(b)

$$\frac{\lim_{\xi \rightarrow \bar{y}^+} \frac{d\mathbb{P}[SA|Y^*=y^*]}{dy^*} \Big|_{y^*=\xi} - \lim_{\xi \rightarrow \bar{y}^-} \frac{d\mathbb{P}[SA|Y^*=y^*]}{dy^*} \Big|_{y^*=\xi}}{\lim_{\xi \rightarrow \bar{y}^+} \frac{d\mathbb{E}[B^*|Y^*=y^*]}{dy^*} \Big|_{y^*=\xi} - \lim_{\xi \rightarrow \bar{y}^-} \frac{d\mathbb{E}[B^*|Y^*=y^*]}{dy^*} \Big|_{y^*=\xi}} \quad (D.1)$$

$$= \int \frac{\partial \mathbb{P}[SA | B = b(\bar{y}, v), Y = \bar{y}, \varepsilon = e]}{\partial B} \cdot \varphi(e, v) dF_{\varepsilon, \nu}(e, v)$$

⁴⁴[Gelber et al. \(2020\)](#) also use imputation for the first-stage of their RKD. The key idea, as in their paper, is that this imputation generates measurement error in the first-stage as well. The [Card et al. \(2015\)](#) framework can account for this measurement error.

where weighting function

$$\varphi(e, v) = \frac{\mathbb{P}[U_Y = 0|Y = \bar{y}, \varepsilon = e, \nu = v](b_1^+(v) - b_1^-(v)) \frac{f_{Y|\varepsilon=e, \nu=v}(\bar{y})}{f_Y(\bar{y})}}{\int \mathbb{P}[U_Y = 0|Y = \bar{y}, \varepsilon = e, \nu = \omega](b_1^+(v) - b_1^-(v)) \frac{f_{Y|\varepsilon=e, \nu=\omega}(\bar{y})}{f_Y(\bar{y})} dF_\nu(\omega)} \quad (\text{D.2})$$

The fuzzy RKD estimates a weighted average of marginal effects of B on $\mathbb{P}[SA]$ with weights $\varphi(e, v)$. The intuition is as follows. $\varphi(e, v)$ has three main components. $\frac{f_{Y|\varepsilon=e, \nu=v}(\bar{y})}{f_Y(\bar{y})}$ is the weight in a sharp RKD and reflects the relative likelihood an individual is located at the kink. $b_1^+(v) - b_1^-(v)$ reflects size of the kink: the fuzzy RKD upweights people with larger kinks. $\mathbb{P}[U_Y = 0|Y = \bar{y}, \varepsilon = e, \nu = v]$ reflects the probability that the assignment variable is correctly measured at threshold.

The [Card et al. \(2015\)](#) identification assumptions are stated in full in [Appendix D.4](#). Two are key to my setting. (a) the density of Y^* is continuously differentiable at the threshold \bar{y} , (b) the benefits-schedule is continuous $\implies \mathbb{P}[\text{Exemption}|Y = y]$ continuous at \bar{y} .

[Figure D.6](#) and [Figure 11](#) show no evidence for non-smoothness of the distribution of income. Discontinuous $\mathbb{P}[\text{Exemption}|Y = y]$ would imply discontinuous $\mathbb{E}[B|SA, Y = y]$ at the threshold. However, [Figure D.2](#) exhibits no such discontinuity. Moreover, there are no conditions in the law which state income below/above the threshold should be exempted differently.

D.2. Estimation. I use monthly data for the regression kink design because eligibility is based on the previous month's income, making granular analysis crucial. While the data provide detailed monthly information on labor income and contracted hours, income from other benefits is only available yearly, which motivates my sample restrictions:

Sample Restrictions: I restrict the sample to individuals working more than zero hours and whose primary income is from work, to avoid notches in the benefit schedule (e.g., disability benefits) tied to the social assistance (SA) eligibility threshold. This threshold corresponds to the social minimum, which links to other government programs. Therefore, individuals who derive all their income from other benefits are ineligible for SA and are excluded. The typical person at the threshold earns most of their income from work/self-employment, with potential supplementary benefits, making them likely to move above or below the threshold at any point.

I further restrict the sample to singles before 2015, as misclassification near the threshold is more common for couples, and limit the period after the Participation Act to ensure the analysis is unaffected by changes in ordeal requirements.

Specification: I estimate a standard fuzzy RKD specification, using local linear regression. I use a [Calonico et al. \(2014\)](#) (hereafter, CCT) robust bandwidth of approximately €80. For the CCT bandwidth selection algorithm, I do not use regularization. This is because the CCT framework is not designed to efficiently identify heterogeneous RKDs nor account for measurement error. Both would suggest the use of a larger bandwidth.⁴⁵ The non-regularized CCT bandwidth delivers a larger bandwidth and has the same asymptotic properties as with regularization. The specification is as follows, where the IV estimate $\frac{\hat{\beta}_1}{\hat{\delta}_1}$ measures $\frac{\partial \mathbb{P}[SA|Y=\bar{y}]}{\partial B}$. I cluster standard-errors at the municipality level.

FIGURE D.2. Plot of benefits received conditional on receipt, averaged within income slice (10EUR bins). A window of 1000EUR either side of the threshold is shown.

D.3. Income Exemptions. I model the unobserved benefits schedule as [Equation \(D.3\)](#).

⁴⁵Indeed, the CCT robust bandwidth without regularization performs poorly in simulations (see [Appendix D.5](#)).

$$B = b(y, \nu) = \begin{cases} \bar{y} & \text{if exemption, } \nu = 1 \\ \max\{\bar{y} - y, 0\} & \text{if exemption, } \nu = 0 \end{cases} \quad (\text{D.3})$$

where $\nu = 1$ with probability $p(y)$. This approach is motivated by the fact that $\mathbb{E}[B|SA, Y = y] \approx \bar{y}$ for $y \geq \bar{y}$. People with income above the threshold are not eligible for any benefits unless they receive an exemption, therefore $\mathbb{E}[B|SA, Y = y]$ is a good measure of benefits received conditional on exemption when $y \geq \bar{y}$. I allow for the possibility that exemptions can vary in reduced-form likelihood throughout the income distribution.

Proposition D.2 (Benefits-Schedule Imputation). *Suppose that the benefits-formula is given by Equation (D.3). Then, $\mathbb{E}[B|Y = y] = p(y) \cdot \bar{y} + (1 - p(y)) \cdot \max\{\bar{y} - y, 0\}$ where:*

$$p(y) = \begin{cases} \frac{(\mathbb{E}[B|SA, Y=y] - (\bar{y} - y)) \cdot \mathbb{P}[SA|Y=y]}{y \cdot \mathbb{P}[SA|Y=y, \nu=1]} & \text{if } y \leq \bar{y} \\ \frac{\mathbb{E}[B|SA, Y=y] \cdot \mathbb{P}[SA|Y=y]}{\bar{y} \cdot \mathbb{P}[SA|Y=y, \nu=1]} & \text{if } y \geq \bar{y} \end{cases} \quad (\text{D.4})$$

The proof is a simple application of Bayes-rule. I proxy $\mathbb{P}[SA|Y = y, \nu = 1] \approx \mathbb{P}[SA|Y = 0]$: the take-up rate conditional on exemption is equal to the take-up rate for people who have no income ($\approx 100\%$).

Proof of Proposition D.2. Let $\mathbb{E}_y \triangleq \mathbb{E}[\cdot|Y = y]$ and $\mathbb{P}_y \triangleq \mathbb{P}(\cdot|Y = y)$

$$\begin{aligned} \mathbb{E}[B|SA, Y = y] &= \mathbb{E}_y[B|SA] \\ &= \frac{\mathbb{E}_y[B \cdot \mathbf{1}\{SA\}]}{\mathbb{P}_y[SA]} \\ \mathbb{E}_y[B \cdot \mathbf{1}\{SA\}] &= \mathbb{E}_y[B \cdot \mathbf{1}\{SA\} \cdot \mathbf{1}\{\nu = 1\}] + \mathbb{E}_y[B \cdot \mathbf{1}\{SA\} \cdot \mathbf{1}\{\nu = 0\}] \\ &= \bar{y} \cdot \mathbb{P}_y[SA \cap \nu = 1] + \max\{\bar{y} - y, 0\} \cdot \mathbb{P}_y[SA \cap \nu = 0] \\ &= \bar{y} \cdot \mathbb{P}_y[SA \cap \nu = 1] + \max\{\bar{y} - y, 0\} \cdot [\mathbb{P}_y[SA] - \mathbb{P}_y[SA \cap \nu = 1]] \end{aligned}$$

Note that $\mathbb{P}_y[\nu = 1] = p(y)$.

$$\begin{aligned}
&= \bar{y} \cdot p(y) \cdot \mathbb{P}_y[SA|\nu = 1] + \max\{\bar{y} - y, 0\} \cdot [\mathbb{P}_y[SA] - p(y) \cdot \mathbb{P}_y[SA|\nu = 1]] \\
&= \begin{cases} [\bar{y} - y] \cdot \mathbb{P}_y[SA] + y \cdot p(y) \cdot \mathbb{P}_y[SA|\nu = 1] & \text{if } y \leq \bar{y} \\ \bar{y} \cdot p(y) \cdot \mathbb{P}_y[SA|\nu = 1] & \text{if } y \geq \bar{y} \end{cases} \\
\text{Therefore, } \mathbb{E}_y[B|SA] &= \begin{cases} \frac{[\bar{y} - y] \cdot \mathbb{P}_y[SA] + y \cdot p(y) \cdot \mathbb{P}_y[SA|\nu = 1]}{\mathbb{P}_y[SA]} & \text{if } y \leq \bar{y} \\ \frac{\bar{y} \cdot p(y) \cdot \mathbb{P}_y[SA|\nu = 1]}{\mathbb{P}_y[SA]} & \text{if } y \geq \bar{y} \end{cases}
\end{aligned}$$

Rearranging for $p(y)$ gives the expression in [Equation \(D.4\)](#).

□

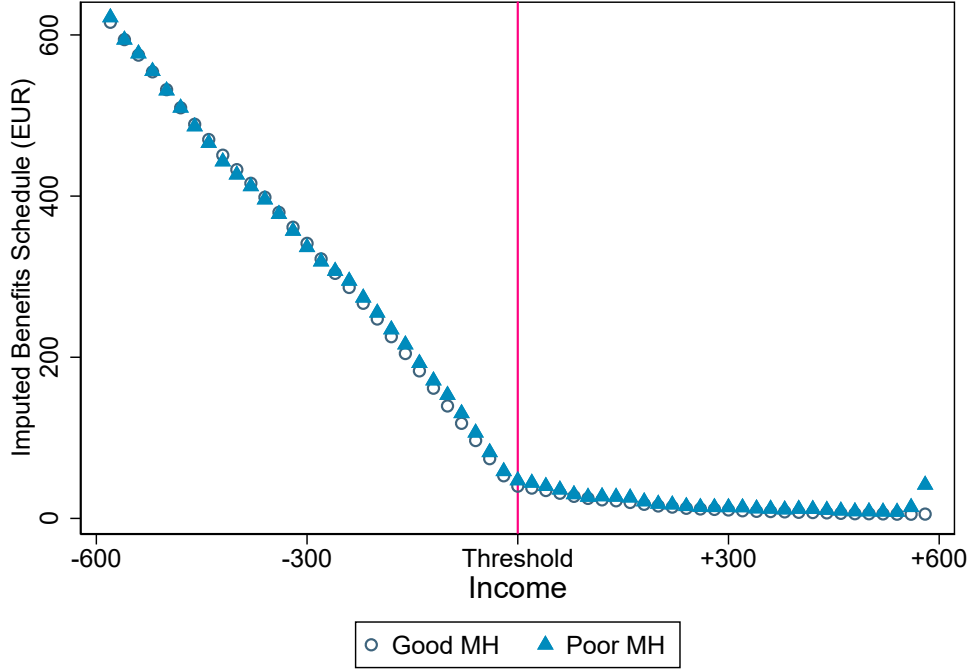

FIGURE D.3. Results of Imputation from [Proposition D.2](#)

D.4. [Card et al. \(2015\)](#) assumptions for validity of fuzzy RKD.

- (1) **Regularity:** (ε, ν) has bounded support. $p(\cdot, \cdot, \cdot)$ is **continuous** and partially differentiable w.r.t. first and second arguments. $p_1(b, y, e)$ continuous.
- (2) **Smooth effect of Y :** $p_2(b, y, e)$ is continuous.

- (3) **First Stage and Nonnegligible Population at Kink:** $b(y, v)$ continuous and $b_1(y, v)$ continuous apart from at $y = \bar{y}$. Positive mass at kink.
- (4) **Smooth Density:** Density of Y is continuously differentiable
- (5) **Smooth Probability of No Measurement Error:** $\mathbb{P}[U_Y = 0, U_B = 0|Y = y, \varepsilon, \nu]$ and partial derivative w.r.t. y is continuous.
- (6) **Monotonicity:** Either $b_1^+(v) \geq b_1^-(v)$ for all v or $b_1^+(v) \leq b_1^-(v)$ for all v .

There are two conditions for identification specific to my context worth highlighting: [Assumption 1](#) and [Assumption 2](#)

Assumption 1 (No 0-censoring).

- (a) Take-up is not censored to 0 below threshold:

$$\forall \mathbb{P}[SA|B = b, Y \leq \bar{y}] > 0 \quad (\text{D.5})$$

- (b) Take-up is not censored to 0 above threshold:

$$\exists \Delta > 0 \text{ s.t. } \mathbb{P}[SA|Y = y] > 0 \forall y \in [\bar{y}, \bar{y} + \Delta] \quad (\text{D.6})$$

Assumption 2 (Continuous probability of exemption).

$$\mathbb{P}[\text{Exemption}|Y = y] \text{ continuous at } \bar{y} \quad (\text{D.7})$$

Without both parts of [Assumption 1](#), the numerator of the estimand in [Equation \(D.1\)](#) will be 0, while without one part only, regularity is violated. In my sample, around 8% of people receiving social assistance have $Y_{\text{true}} > \bar{y}$. ?? provides support that $\lim_{B \rightarrow 0} \mathbb{P}[SA|B] > 0$. [Assumption 2](#) is a corollary of $b(y, v)$ being continuous.

D.5. Estimation Choices. To assess the performance of the CCT robust bandwidth in my context, I perform simulation analyses on a simplified version of the model set out in [Section 2](#). The motivation for these analyses is that the frameworks are not designed for (i) measurement error and (ii) efficiently detecting heterogeneous RKD effects.

D.5.1. Setup. I simulate a million individuals which are characterised by ability $Y \sim U[500, 1500]$. This corresponds to their income. I set a fixed cost to be $\kappa = 150$ for everyone. Choice error $\varepsilon = \frac{U_1 + U_2}{2}$ where $U_j \stackrel{\text{i.i.d.}}{\sim} U[-200, 200]$. I.e. ε follows a symmetric

triangular distribution centered around 0. The threshold $\bar{y} = 1000$ for everyone. Benefits schedule $B(y)$ is programmed as $B(y) = \max\{\bar{y} - \nu \cdot y, 0\}$ where exemption $\nu \in \{0, 1\}$ and $\mathbb{P}[\nu = 1|Y = y] \equiv 0.1$. Individual y takes up iff:

$$B(y) \geq \kappa \quad (\text{D.8})$$

In the case of measurement error, I let $Y^* = Y + U_Y$ where $U_Y \sim N(0, 100)$. I then run the CCT robust bandwidth and RKD analyses exactly as in the main analysis. Specifically, I impute the benefits schedule as in [Proposition D.2](#). The results of this imputation are shown in ??.

D.5.2. Results.

Polynomial order: applying rules-of-thumb from [Pei et al. \(2022\)](#) suggests a linear estimator. Furthermore, simulations show that with measurement-error - linear estimators out-perform higher order polynomials at the CCT robust optimal bandwidth. This result echoes [Card et al. \(2015\)](#) who suggests that the CCT bandwidths can be too small for RKDs.

Bandwidth: for linear estimation, CCT bandwidths seem to perform well, but estimates become noisy for lower values with measurement error. For the identification of heterogeneous effects under measurement error, CCT performs poorly: I now assume that half of my simulated individuals have value $\alpha = 1$, and half $\alpha = 2$. Individuals take-up iff:

$$\alpha \cdot B(y) \geq \kappa \quad (\text{D.9})$$

and rate of receipt $\mathbb{P}[SA|Y = y] = F_\epsilon(\alpha \cdot B(y) - \kappa)$. I estimate the RKDs separately for $\alpha = 1, 2$ and test for a difference in the RKD estimates at different bandwidths. The estimates are shown in [Figure D.5](#). The plot shows that the CCT bandwidth performs poorly (noisy and biased estimate of the heterogeneous RKD), whereas the estimators converge to the true effect for larger bandwidths.

Other: use standard triangular kernel.

D.6. Validity of RKD.

D.7. Results.

(A) Local polynomial order $p = 1$

(B) Local polynomial order $p = 2$

(C) Local polynomial order $p = 3$

FIGURE D.4. Results of simulations showing estimates from RKDs using different bandwidths and different local polynomial orders. In each, the CCT robust bandwidth is shown.

FIGURE D.5. Results of simulations showing estimates from heterogeneous RKD ($\alpha = 1$ vs 2) using different bandwidths. CCT robust bandwidth is shown.

FIGURE D.6. Density of income around the eligibility threshold. [McCrary \(2008\)](#) tests for discontinuity in levels and slopes around the threshold are shown. Income in this plot is monthly. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions.

FIGURE D.7. Covariate Test: plot shows fitted values of a regression of social assistance take-up on all pre-determined controls used throughout this paper including income, education, hh composition, municipality FEs. These fitted values form a “Covariate Index” which is binned. An RKD estimate with income as the running variable is also shown. Income in this plot is monthly. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Standard-errors are clustered at the municipality level.

FIGURE D.8. Covariate Test: plot shows fitted values of a regression of social assistance take-up on all pre-determined controls used throughout this paper including income, education, hh composition, municipality FEs. These fitted values form a “Covariate Index” which is binned. An RKD estimate with income as the running variable is also shown. Separated by mental health. Income in this plot is monthly. Poor mental health is defined as receiving psychopharma in the year previously. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Regression lines are shown following [Section 6.1.2](#), as well as the estimated change in slopes following the regression kink design. Standard-errors are clustered at the municipality level.

FIGURE D.9. Results of permutation test à la [Ganong and Jäger \(2018\)](#). I estimate RKDs on 100 placebo kinks in the range $[\bar{y} - 600, \bar{y} + 600]$ and plot a histogram of the estimates. A binomial test is used to check whether the true estimate is an outlier. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Standard-errors are clustered at the municipality level.

FIGURE D.10. Results of test of sensitivity to changes in bandwidth. I estimate RKDs changing the bandwidth, with the CCT robust bandwidth displayed. The lower purple dashed line indicates the CCT robust bandwidth with regularization, and the upper pink dashed line indicates the CCT robust bandwidth without regularization. This plot shows the estimates and confidence intervals. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Standard-errors are clustered at the municipality level.

FIGURE D.11. Results of test of sensitivity to changes in bandwidth. I estimate heterogeneous RKDs changing the bandwidth, with the CCT robust bandwidth displayed. The lower purple dashed line indicates the CCT robust bandwidth with regularization, and the upper pink dashed line indicates the CCT robust bandwidth without regularization. This plot shows the estimates and confidence intervals. Poor mental health is defined as receiving psychopharma in the year previously. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Standard-errors are clustered at the municipality level.

FIGURE D.12. Average rate of receipt within income slice in a small window of income either side of the eligibility threshold. Income in this plot is monthly. The sample contains singles employees, years 2011-2014. See [Section 6.1.2](#) for details on sample restrictions. Regression lines are shown following [Section 6.1.2](#), as well as the estimated change in slopes following the regression kink design. Standard-errors are clustered at the municipality level.

TABLE D.1. Estimates from the regression kink design using a bandwidth of €80. Columns 2 - 5 show the reduced-form and 6 - 9 IV. Columns 2 and 3 show estimates of the slope of receipt of SA w.r.t income - both below and above the threshold. Column 2 reflects estimates without any covariates. In Column 3, I add controls for month, year, age, gender, wealth, education, municipality, hh composition and sector fixed effects. Columns 4 and 5 show heterogeneous estimates by mental health (without / with controls respectively). "Income - Threshold" reflects the results for people with good mental health, and "Income - Threshold (het)" that of poor mental health (relative to good). Analogously columns 6 - 9 are the IV estimates using the imputed benefits schedule as a first-stage. Throughout, standard-errors are clustered at the municipality level. Underlying population = singles 2011-2014 who get most income from work. See text for details.

APPENDIX E. CALIBRATION OF WELFARE EFFECTS: ADDITIONAL MATERIAL

E.1. Eligibility. Throughout the empirical analysis, I focus on take-up levels and responses among the *eligible* population. This is because I am interested in take-up *behaviour* across types, and not underlying eligibility. However, the theoretical framework above does not model eligibility directly. Indeed, the government budget constraint as defined in Equation (2.4) makes much more sense if it holds for θ in the general population, and not the eligible. In reality, the ineligible fund benefits for the recipients, and not the eligible non-takers.

Proposition E.1 shows that identifying take-up levels and responses for the eligible population is sufficient for the general population as long as $\mathbb{P}[SA|Ineligible] = 0$.

Proposition E.1. Assume $\mathbb{P}[SA|Ineligible] = 0$. Then:

$$\mathbb{P}[SA]_\theta = \mathbb{P}[SA | Eligible]_\theta \cdot \mathbb{P}[Eligible]_\theta \quad (\text{E.1})$$

and take-up responses to policy X are given by:

$$\frac{\partial \mathbb{P}[SA]_\theta}{\partial X} = \frac{\partial \mathbb{P}[SA | Eligible]_\theta}{\partial X} \cdot \underbrace{\left(\frac{\mathbb{P}[Eligible]_\theta}{1 - \mathbb{P}[SA | Eligible]_\theta \cdot \mathbb{P}[Ineligible | No SA]_\theta} \right)}_{EE_\theta: \text{Effective Eligibility}_\theta} \quad (\text{E.2})$$

Proposition E.1 follows from Bayes Rule, the fact that eligibility is determined by $y \leq \bar{y}$ where $y = SA \cdot y^{SA=1} + (1 - SA) \cdot y^{SA=0}$ and from the fact we have assumed no labor supply responses to dB or $d\Lambda$. The intuition is as follows: we need to adjust for baseline incomplete take-up and the fact that ineligible people can still be on the margin of take-up (if they were just indifferent between earning income above the threshold and switching to earning income below the threshold and receiving social assistance) when mapping conditional take-up responses to the general population.

How should we implement Proposition E.1 when calculating welfare effects? When integrating against average take-up levels, Bayes Rule $\rightarrow \int \mathbb{P}[SA]_\theta \cdot H_\theta d\mu = \mathbb{P}[Eligible] \cdot$

$\int \mathbb{P}[SA \mid \text{Eligible}]_\theta \cdot H_\theta d\mu_{\text{Eligible}}$. Where μ_{Eligible} is the conditional density of types θ . Similarly, Bayes Rule $\rightarrow \int \frac{\partial \mathbb{P}[SA]_\theta}{\partial X} \cdot H_\theta d\mu = \mathbb{P}[\text{Eligible}] \cdot \int \frac{\partial \mathbb{P}[SA|\text{Eligible}]_\theta}{\partial X} \cdot \frac{1}{1 - \mathbb{P}[SA \mid \text{Eligible}]_\theta \cdot \mathbb{P}[\text{Ineligible} \mid \text{No } SA]_\theta} \cdot H_\theta d\mu_{\text{Eligible}}$.

| Sufficient Statistics | Method | Estimated Value |

TABLE E.1. Table summarising the calibration of the key sufficient statistics

FIGURE E.1. Comparison of RKD Overview and RKD Psych

E.2. Identification.

E.3. Relaxing Modelling Assumptions. Relaxing additivity involves assuming $SA = 1 \iff v_\theta(B, \varepsilon) > \kappa_\theta(\Lambda, \varepsilon)$. Given monotonicity in ε , behaviour will still follow a threshold-rule. Marginal entrants have ε_θ^* which satisfies the implicit equation $v_\theta(B, \varepsilon_\theta^*) =$

$\kappa_\theta(\Lambda, \varepsilon_\theta^*)$. Without additivity, a bounding argument can be made about $\frac{dW}{d\Lambda}$ following [Haller and Staubli \(2024\)](#).

Relaxing independence of ε leads to the following. Suppose we used the model of [Rafkin et al. \(2023\)](#) where $v'_\theta(B)$ is independent of θ conditional on income, but $\varepsilon_\theta \sim F_\theta$. Then, same average take-up levels combined with the difference-in-differences results would suggest $f_{\varepsilon_L}(v_L - \kappa_L) = 1.65 \times f_{\varepsilon_H}(v_H - \kappa_H)$, inconsistent with the regression kink design results. Using [Finkelstein and Notowidigdo \(2019\)](#)'s model, κ'_θ are assumed to be opportunity costs of time, the only reason why need would vary across individuals with the same income is due to misperceptions of the benefit level and $\varepsilon_\theta \sim F_\theta$. My results would then suggest $\kappa'_L = w_L = \text{€}11.7$ and $\kappa'_H = w_H = \text{€}13.7$, where w_θ is θ 's wage. Then, the regression kink design estimates would suggest $v'_L = 1.8 \times v'_H$. This would imply that people with poor mental health have an easier time overcoming barriers, and are substantially *less* pessimistic about the benefit level. Both of these results contradict psychological evidence ([Martin et al., 2023b](#); [Evans et al., 2014](#); [Alloy and Ahrens, 1987](#)).

Details: Assume linearity: $v_\theta(B) = v_\theta \cdot B$ and $\kappa_\theta(\Lambda) = \kappa_\theta \cdot \Lambda$. Note that one or other of these assumptions is assumed throughout in [Anders and Rafkin \(2022\)](#), [Finkelstein and Notowidigdo \(2019\)](#) and [Rafkin et al. \(2023\)](#). In this case: $\hat{\mathbb{P}}[SA]_L \approx \hat{\mathbb{P}}[SA]_H \implies v_L \cdot B - \kappa_L \cdot \Lambda = v_H \cdot B - \kappa_H \cdot \Lambda$. This means that $\kappa_L - \kappa_H = \frac{v_L \cdot B - v_H \cdot B}{\Lambda}$. Recall that $\frac{\partial \hat{\mathbb{P}}[SA]_H}{\partial B} = 0.00028$ and $\frac{\partial \hat{\mathbb{P}}[SA]_L}{\partial B} = 2.3 \times 0.00028$. These estimates imply $\kappa_L - \kappa_H = \frac{2.3 \times 874.54 - 865.27}{\Lambda}$.

Let $f_\varepsilon^{d\Lambda} = \alpha \cdot f_\varepsilon^{dB}$ - i.e. assume that the ratio of the probability of being marginal to a benefits-level instrument over probability of being marginal to an ordeal change is constant across mental health types. In this case, $\frac{\partial \hat{\mathbb{P}}[SA]_L - \hat{\mathbb{P}}[SA]_H}{\partial \Lambda} = -(\kappa_L - \kappa_H) \cdot \alpha \cdot 0.00055$, as $\frac{\partial \hat{\mathbb{P}}[SA]_H}{\partial B} = f_\varepsilon^{dB}$. Rearranging for α ,

$$\hat{\alpha} = \frac{-\Lambda \frac{\partial \hat{\mathbb{P}}[SA]_L - \hat{\mathbb{P}}[SA]_H}{\partial \Lambda}}{0.00028 \times 945.03} \quad (\text{E.3})$$

Therefore as long as we can estimate the heterogeneous semi-elasticity $-\Lambda \frac{\partial \hat{\mathbb{P}}[SA]_L - \hat{\mathbb{P}}[SA]_H}{\partial \Lambda}$, we are done.

I use [Table C.1](#) to calibrate the percent change in ordeals $\frac{\partial \Lambda}{\Lambda} = 22.1\%$ - which comes from treating the final column as percent changes in each of the scores (second column) where the score cannot exceed 100%. Therefore,

$$\begin{aligned}
-\Lambda \frac{\partial \hat{\mathbb{P}}[SA]_L - \hat{\mathbb{P}}[SA]_H}{\partial \Lambda} &= \frac{0.09}{0.221} = 0.040 \\
\implies \hat{\alpha} &= \frac{0.040}{0.52} = 0.077
\end{aligned}$$

In particular, $f^{d\Lambda} < f^{dB}$ - which only pushes in the direction of $MVPF_{d\Lambda} > MVPF_{dB}$.

Assumption (ii) follows in the case that types are one-dimensional (Landais et al., 2021). However, note that to maximise internal validity of the quasi-experimental design, sample restrictions are made both in Section 5 and Section 6. In Section 5, I focus on couples, as for them, the Participation Act was a change in ordeals only, and not also a change in benefit level. Note that the majority of individuals in this sample have income much below the threshold. In Section 6, I focus on singles, as I mis-classify couples more than singles, and in the RKD analysis, measurement error is much more consequential, because I zoom into a small window around the threshold. Moreover, I restrict to people who earn most of their money from work - as there are notches in the schedules of other benefits at the social minimum = social assistance eligibility threshold. The samples for the two instruments are quite different, and the within-sample compliers may be even more different across instruments (as in Landais et al. (2021)). This is an important caveat.

However, my framework is flexible enough to relax this assumption under structural assumptions. Recall that the partial-identification result described in ?? does *not* rely on the benefit-level response estimated in Section 6. If people with poor mental health receive SA at the same rate as those with good mental health, but are more likely to be screened out by ordeals, they must value the benefit more. In Appendix E, I employ some additional structure in order to use the correlation test to identify net value – cost, which then allows for the quantification of all sufficient statistics without maintaining Assumption (ii). I find that in the structural model, the probability of being marginal to a barrier instrument is about 1/4 to that of a benefits instrument - this only pushes the welfare comparison that I explore in the next section *more* to the side of reducing barriers.

Such a stark difference in $MVPFs$ generates confidence that the modelling assumptions are not what drives $MVPF_{d\Lambda} > MVPF_{dB}$. Note that $MVPF_{d\Lambda}$ is roughly proportional to κ' and $1/f_\varepsilon^{d\Lambda}(\cdot)$ holding all else fixed. This means that $\mathbb{P}[\text{Marginal to Ordeal}]$

$\text{Change}]_\theta > 2.1 \times \mathbb{P}[\text{Marginal to Benefits Change}]_\theta$ in order to reverse the welfare comparison.⁴⁶

E.4. Welfare Effects. Calculating social marginal utilities of beneficiaries of benefit and barrier change instruments:

$$\bar{\eta}_{dB} = 0.25 \times 2.07 + 0.73 \times 1$$

$$\approx 1.29$$

$$\bar{\eta}_{d\Lambda} = 0.25 \times 2.07 \times \frac{36.2/2.07}{0.25 \times 36.2/2.07 + 0.73 \times 20.2} + 0.73 \times 1 \times \frac{20.2}{0.25 \times 36.2/2.07 + 0.73 \times 20.2}$$

$$\approx 1.26$$

E.5. Robustness to Bias. Suppose a share ψ of $\kappa_\theta(\Lambda)$ is a true cost, and $(1 - \psi)$ is a hassle cost, which affects behaviour but not welfare. Then: $\mathbb{P}[SA]_\theta = F_\varepsilon[v_\theta(B) - \kappa_\theta(\Lambda)]$ still, but:

$$\mathcal{U}_\theta = \int_{-\infty}^{\varepsilon_\theta^*} [v_\theta(B) - \kappa_\theta(\Lambda) + MI_\theta - \varepsilon] dF(\varepsilon) \quad (\text{E.4})$$

where $\varepsilon_\theta^* = v_\theta(B) - \kappa_\theta(\Lambda)$ and $MI_\theta = (1 - \psi) \cdot \kappa_\theta(\Lambda)$ is the marginal internality (Mullainathan et al., 2012). Note that since the true cost $\psi \cdot \kappa \leq \kappa$, behaviour over-states the ordeal-cost, so take-up is too low relative to the private optimum. This means that a marginal increase in Λ has an extra negative behavioural welfare cost coming from people moving further away from the private optimum. A marginal increase in B has an extra positive behavioural welfare gain coming from the internality correction. This is shown in Proposition E.2.

Proposition E.2. *First order welfare effects when perceived cost differs from true cost.*

$$\frac{d\mathcal{U}_\theta}{d\Lambda} = -\psi \cdot \kappa'_\theta(\Lambda) \cdot \mathbb{P}[SA]_\theta + MI_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial \Lambda} \quad (\text{E.5})$$

$$\frac{d\mathcal{U}_\theta}{dB} = v'_\theta(B) \cdot \mathbb{P}[SA]_\theta + MI_\theta \cdot \frac{\partial \mathbb{P}[SA]_\theta}{\partial B} \quad (\text{E.6})$$

⁴⁶In fact, as shown in Appendix E, $\mathbb{P}[\text{Marginal to Ordeal Change}]_\theta = \mathbb{P}[\text{Marginal to Benefits Change}]_\theta$ is actually a conservative assumption. Under linearity of v_θ and κ_θ , the correlation test leads me to estimate the probability of being marginal being lower ($\approx 15\%$) for the ordeal instrument than for the benefits-level change.

Proof.

$$\mathcal{U}_\theta = \int_{-\infty}^{\varepsilon_\theta^*} [v_\theta(B) - \kappa_\theta(\Lambda) - \varepsilon] dF(\varepsilon) + \int_{-\infty}^{\varepsilon_\theta^*} MI_\theta dF(\varepsilon)$$

which means that, by the Leibniz integral rule:

$$\frac{d\mathcal{U}_\theta}{d\Lambda} = -\kappa'_\theta(\Lambda) \cdot F(\varepsilon_\theta^*) + 0 + (1 - \psi)\kappa_\theta(\Lambda) \frac{\partial F(\varepsilon_\theta^*)}{\partial \Lambda} + (1 - \psi)\kappa'_\theta(\Lambda) \cdot F(\varepsilon_\theta^*)$$

where the 0 comes from $\varepsilon_\theta^* = v_\theta(B) - \kappa_\theta(\Lambda)$ - this is the Envelope Theorem at play. Rearranging gives [Equation \(E.5\)](#). Similarly,

$$\frac{d\mathcal{U}_\theta}{dB} = v'_\theta(B) \cdot F(\varepsilon_\theta^*) + 0 + (1 - \psi)\kappa_\theta(\Lambda) \frac{\partial F(\varepsilon_\theta^*)}{\partial B}$$

and there is no final term because MI_θ is independent of B . \square

These first order effects imply new MVPF formulas for the welfare effect of changing benefits and barriers. The fiscal externalities are unchanged - since they depend on behaviour only. However, the direct welfare effects reflect [Equations \(E.5\)](#) and [\(E.6\)](#).

Corollary E.1. *With bias:*

$$MVPF_{d\Lambda} = \frac{-\psi \cdot \int \lambda \cdot \frac{\kappa'_\theta(\Lambda)}{v'_\theta(B)} \mathbb{P}[SA] d\mu - (1 - \psi) \cdot \int \lambda \frac{\kappa(\Lambda)}{v'_\theta(B)} \frac{\partial \mathbb{P}[SA]}{\partial \Lambda} d\mu}{\int FE \cdot \frac{\partial \mathbb{P}[SA]}{\partial \Lambda} d\mu} \quad (\text{E.7})$$

$$MVPF_{dB} = \frac{\int \lambda \mathbb{P}[SA] d\mu + (1 - \psi) \cdot \int \lambda \frac{\kappa(\Lambda)}{v'_\theta(B)} \frac{\partial \mathbb{P}[SA]}{\partial B} d\mu}{\int FE \cdot \frac{\partial \mathbb{P}[SA]}{\partial B} d\mu} \quad (\text{E.8})$$

E.5.1. Calibration. How does bias affect the quantification of welfare effects? This requires us to evaluate the size of MI_θ , the marginal internality for each type. According to the theory,

$$MI_\theta = (1 - \psi) \cdot \kappa_\theta(\Lambda) \quad (\text{E.9})$$

Note that the marginal internality depends on *average* ordeal-costs, rather than marginal ordeal-costs. In order to evaluate this term, I make the linearization $\kappa_\theta(\Lambda) = \kappa_\theta \cdot \Lambda$. Therefore, evaluating the new *MVPF* formulas requires taking a stance on what Λ is.

As discussed in [Appendix E.3](#), qualitative evidence from municipalities suggests the percent change in Λ due to the Participation Act is an increase of 22.1%. Further, I assume that the Participation Act represented an absolute change in Λ of 1 unit. Therefore, $\Lambda = 1/0.221 = 4.52$. For example, Λ could represent number of hours spent on obligations, and κ_θ is the welfare cost per hour spent. When $\kappa_\theta(\Lambda) = \kappa_\theta \cdot \Lambda$, $\kappa_\theta = \kappa'_\theta(\Lambda)$.

Therefore, given the estimates from [Section 7](#):

$$MI_L = (1 - \psi) \cdot 4.52 \cdot 130 = (1 - \psi) \cdot 590$$

$$MI_H = (1 - \psi) \cdot 4.52 \cdot 79 = (1 - \psi) \cdot 359$$

These estimates mean that we can quantify how large the *MVPF* formulas are for different values of ψ . For $\psi = 1$ - the *MVPF* are as [Section 7](#). What if ordeal-costs were a pure bias which affects behaviour only but not welfare? Then:

$$MVPF_{d\Lambda}^{\psi=0} = 0.30$$

$$MVPF_{dB}^{\psi=0} = 0.96$$

$MVPF_{d\Lambda}^{\psi=0} < MVPF_{d\Lambda}^{\psi=1}$ as there is no direct welfare effect of the increase in barriers. $MVPF_{d\Lambda}^{\psi=0} \neq 0$, however, because of the negative behavioural welfare effect. $MVPF_{dB}^{\psi=0} > MVPF_{dB}^{\psi=1}$ because of the internality correction that an increase in benefits provides. Finally, we can quantify the level of bias ψ^* required to reverse the welfare ordering $MVPF_{d\Lambda} > MVPF_{dB}$. This turns out to be $\psi^* = 44\%$. That is to say, the government needs to be confident that at least 56% of the as-if ordeal-costs are purely a bias in order to reverse the welfare conclusions. Finally, note that $d\Lambda$ is unsurprisingly more sensitive to bias than dB .
